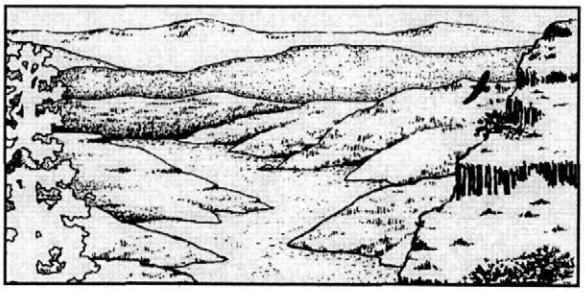
Abstract

Quigley, Thomas M.; Arbelbide, Sylvia J., tech. eds. 1997. An assessment of ecosystem components in the interior Columbia basin and portions of the Klamath and Great Basins: volume 1. Gen. Tech. Rep. PNW-GTR-405. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 4 vol. (Quigley, Thomas M., tech. ed.; The Interior Columbia Basin Ecosystem Management Project: Scientific Assessment).



The *Assessment of Ecosystem Components in the Interior Columbia Basin and Portions of the Klamath and Great Basins* provides detailed information about current conditions and trends for the biophysical and social systems within the Basin. This information can be used by land managers to develop broad land management goals and priorities and provides the context for decisions specific to smaller geographic areas. The Assessment area covers about 8 percent of the U.S. land area, 24 percent of the Nation's National Forest System lands, 10 percent of the Nation's BLM-administered lands, and contains about 1.2 percent of the Nation's population. This results in a population density that is less than one-sixth of the U.S. average. The area has experienced recent, rapid population growth and generally has a robust, diverse economy. As compared to historic conditions, the terrestrial, aquatic, forest, and rangeland systems have undergone dramatic changes. Forested landscapes are more susceptible to fire, insect, and disease than under historic conditions. Rangelands are highly susceptible to noxious weed invasion. The disturbance regimes that operate on forest and rangeland have changed substantially, with lethal fires dominating many areas where non-lethal fires were the norm historically. Terrestrial habitats that have experienced the greatest decline include the native grassland, native shrubland, and old forest structures. There are areas within the Assessment area that have higher diversity than others. Aquatic systems are now more fragmented and isolated than historically and the introduction of non-native fish species has complicated current status of native fishes. Core habitat and population centers do remain as building blocks for restoration. Social and economic conditions within the Assessment area vary considerably, depending to a great extent on population, diversity of employment opportunities, and changing demographics. Those counties with the higher population densities and greater diversity of employment opportunities are generally more resilient to economic downturns. This Assessment provides a rich information base, including over 170 mapped themes with associated models and databases, from which future decisions can benefit.

Keywords: Columbia basin, biophysical systems, social systems, ecosystem.

Preface

This document represents a substantial portion of the work of the Science Integration Team (SIT) of the Interior Columbia Basin Ecosystem Management Project (ICBEMP). This product results from the efforts of literally hundreds of scientists and technical specialists. The SIT provided leadership to the entire effort that took more than three years to complete. Summaries of the work and synthesis products, *An Integrated Assessment of the Interior Columbia Basin and portions of the Klamath and Great Basins* and *Status of the Interior Columbia Basin Ecosystem Management Project Summary of Scientific Findings,* appeared before the formal publication of this document. Combined, these pieces constitute the Scientific Assessment of the Interior Columbia Basin and portions of the Klamath and Great Basins. The Assessment benefitted greatly by interactions with the ICBEMP Environmental Impact Statement Team members and Project Leaders. The open process undertaken through this effort represented a first for such a scientific endeavor. We learned a great deal from the many individuals and groups who took interest in and participated in the many open meetings and presentations held. The products are better because of this openness.

The leadership of Charlie Philpot, Denver Burns, and particularly Tom Mills during the closing months of the process, helped the SIT through the significant internal and external political process that surrounded the ICBEMP process and products. We recognize that existence of the document is a result of Jodi Clifford's efforts and persistence in organizing, coordinating, and editing.

SCIENCE TEAM MEMBERS

Team Leaders

Thomas M. Quigley, Range Scientist, Science Integration Team Leader.USDA Forest Service, Pacific Northwest Research Station, Walla Walla, WA.

Sylvia J. Arbelbide, Geologist, Deputy Science Integration Team Leader.USDA Forest Service, Pacific Southwest Region, San Francisco, CA.

Russell T. Graham, Research Forester, Deputy Science Team Leader.USDA Forest Service, Intermountain Research Station, Moscow, ID.

Aquatics

David Burns, Fisheries Biologist. USDA Forest Service, Intermountain Region, Payette National Forest, McCall, Idaho.

James Clayton, Soil Scientist. USDA Forest Service, Intermountain Research Station, Boise, ID.

Lynn Decker, Biologist, Aquatic Team Co-Leader. USDA Forest Service, Pacific Southwest Region, San Francisco, CA.

Robert Gresswell, Fisheries Biologist. USDI Fish and Wildlife Service, detailed to Pacific Northwest Research Station, Corvallis, OR.

Robert House, Fisheries Biologist. USDI Bureau of Land Management, Idaho State Office, Boise, ID.

Phil Howell, Fisheries Biologist. USDA Forest Service, Pacific Northwest Region, Umatilla National Forest, North Fork Ranger District, Uriah, OR.

Danny C. Lee, Research Biologist, Aquatic Team Leader. USDA Forest Service, Intermountain Research Station, Boise, ID.

Kristene M. Lee, Biologist, Aquatic Team Co-Leader. USDA Forest Service, Intermountain Region, Ogden, UT.

Ken MacDonald, Fisheries biologist USDA Forest Service, Pacific Northwest Region, Wenatchee National Forest, Wenatchee, WA.

John McIntyre, Scientist Emeritus, USDA Forest Service, Intermountain Research Station, Boise, ID.

Shaun McKinney, Fisheries Biologist. USDA Forest Service, Umatilla National Forest, Pendleton, OR.

Tracy Noel, Biological Technician. USDA Forest Service, Pacific Northwest Research Station, Corvallis, OR.

Jim E. O'Connor, Fisheries Biologist, USDA Forest Service, Pacific Northwest Research Station, Walla Walla, WA.

C. Kerry Overton, Technology Transfer Specialist. USDA Forest Service, Intermountain Research Station, Boise, ID.

Doug Perkinson, Fisheries Biologist. USDA Forest Service, Northern Region, Kootenai National Forest, Libby, MT.

James R. Sedell, Research Biologist, Aquatic Team Co-Leader. USDA Forest Service, Pacific Northwest Research Station, Corvallis, OR.

Bruce E. Rieman, Research Fisheries Biologist Service, Intermountain Research Station, Boise, ID.

Russell F. Thurow, Fisheries Research Scientist. USDA Forest Service, Intermountain Research Station, ID.

Jack E. Williams, Aquatic Scientist, Aquatic Team Co-Leader. Bureau of Land Management, Idaho State Office, Boise, ID.

Ken Tu, Forester. USDA Forest Service, Umatilla National Forest, Walla Walla, WA.

Pat Van Eimeren, Fisheries Biologist. USDA Forest Service, Northern Region, Flathead National Forest, Kalispell, ID.

Economics

Richard W. Haynes, Research Forester, Economics Co-Team Leader.USDA Forest Service, Pacific Northwest Research Station, Portland, OR.

Amy L. Horne, Research Forester, Economics Co-Team Leader.USDA Forest Service, Pacific Northwest Research Station, Portland, OR.

Wendy McGinnis, Economist.USDA Forest Service, Pacific Northwest Research Station, Portland, OR.

Nicholas Reyna, Forest Economist.USDA Forest Service, Pacific Northwest Research Station,Walla Walla, WA.

Landscape Ecology

Ann L. Acheson, Air Program Manager.USDA Forest Service, Northern Region, Missoula, MT.

Carl Almquist, Geologist.USDI Bureau of Mines, Western Field Operations Center, Spokane, WA.

Kenneth Brewer, Landscape Ecologist.USDA Forest Service, Flathead National Forest, Kalispell, MT.

Sue Ferguson, Research Climatologist.USDA Forest Service, Pacific Northwest Research Station, Seattle, WA.

Gary L. Ford, Soil Scientist.USDA Forest Service, Idaho Panhandle National Forest, Coeur d'Alene, ID.

Thomas P. Frost, Research Geologist.USDI Geological Survey, Western Mineral Resources Branch, Spokane, WA.

Iris Goodman, Research/Landscape Hydrologist.Environmental Protection Agency, Office of Landscape Characterization Research and Development, Las Vegas, NV.

Wendel J. Hann, Landscape Ecologist, Landscape Ecology Team Co-Leader.USDA Forest Service, Northern Region, Missoula, MT.

Colin Hardy, Supervisory Research Forester.USDA Forest Service, Intermountain Research Station, Missoula, MT.

Paul F. Hessburg, Research Plant Pathologist/Entomologist, Landscape Ecology Team Co-Leader.USDA Forest Service, Pacific Northwest Research Station, Wenatchee, WA.

Mark E. Jensen, Landscape Ecologist/ Landscape Ecology Team Co-Leader.USDA Forest Service, Northern Region, Missoula, MT.

Jeffrey L. Jones, Wildlife Biologist.USDA Forest Service, Beaverhead National Forest, Dillon, MT.

Lynn Kaney, Silviculturist.USDA Forest Service, Colville National Forest, Newport, WA.

Michael G. (Sherm) Karl, Rangeland Management Specialist/Ecologist.USDA Forest Service, Pacific Northwest Research Station, Walla Walla, WA.

Robert E. Keane, System Dynamics/Research Ecologist.USDA Forest Service, Intermountain Research Station, Missoula, MT.

Steve Leonard, Range Conservationist.USDI Bureau of Land Management, Nevada State Office, Reno, NV.

Don Long, Forester.USDA Forest Service, Intermountain Research Station, Missoula, MT.

Mary E. Manning, Ecologist.USDA Forest Service, Northern Region, Missoula, MT.

Cecilia McNicoll, Ecological Analyst/Inventory.USDA Forest Service, Intermountain Research Station, Missoula, MT.

James P. Menakis, Forester.USDA Forest Service, Intermountain Research Station, Missoula, MT.

John Nesser, Soil Scientist.USDA Forest Service, Northern Region, Missoula, MT.

Roger Ottmar, Research Forester.USDA Forest Service, Pacific Northwest Research Station, Seattle, WA.

David Powell, Forest Silviculturist.USDA Forest Service, Umatilla National Forest, Pendleton, OR.

Bradley G. Smith, Quantitative Community Ecologist.USDA Forest Service, Pacific Northwest Research Station, Bend, OR.

Mike Stimak, Forester.USDI Bureau of Land Management, Upper Columbia-Salmon and Clearwater Districts, Coeur d'Alene, ID.

Social

Stewart D. Allen, Sociologist.USDA Forest Service, Pacific Northwest Research Station, Walla Walla, WA.

Jon S. Bumstead, Social Scientist, Social Science Team Co-Leader.USDA Forest Service, Pacific Northwest Research Station, Walla Walla, WA.

James A. Burchfield, Sociologist, Social Science Team Co-Leader.USDA Forest Service, Pacific Northwest Research Station, Walla Walla, WA.

Steven J. Galliano, Landscape Architect.USDA Forest Service, Pacific Northwest Research Station, Walla Walla, WA.

Richard C. Hanes, Anthropologist/Native American Topics Specialist.USDI Bureau of Land Management, Oregon/Washington State, Eugene, OR.

Gary Loeffler, Landscape Architect.USDA Forest Service, Mt. Hood National Forest, Zigzag, OR.

Steven F. McCool, Social Scientist, Social Science Team Co-Leader.USDA Forest Service, Pacific Northwest Research Station, Walla Walla, WA.

Joan Trent, Attitudes/Values/Beliefs Specialist.USDI Bureau of Land Management, Montana State Office, Billings, MT.

Spatial

Becky Gravenmier, Natural Resource Specialist/GIS, Spatial Team Leader.USDI Bureau of Land Management, Oregon/Washington State Office,Portland, OR.

John Steffenson, GIS Specialist.USDA Forest Service, Pacific Northwest Region, Portland, OR.

Andrew Wilson, GIS Specialist.USDA Forest Service, Pacific Northwest Region, Portland, OR.

Terrestrial

Katie Boula, Wildlife Biologist.USDA Forest Service, Umatilla National Forest, Pendleton, OR.

Michael A. Castellano, Research Forester.USDA Forest Service, Pacific Northwest Research Station, Corvallis, OR.

Lisa Croft, Botanist, Vascular and Non-Vascular Plants Group Leader.USDA Forest Service, Ochoco National Forest, Prineville, OR.

Michelle Eames, Wildlife Biologist.USDI Fish and Wildlife Service, Spokane, WA.

Christina Hargis, Wildlife Ecologist.USDA Forest Service, Intermountain Research Station, Logan, UT.

Randal J. Hickenbottom, Wildlife Biologist, Terrestrial Team Co-Leader.USDA Forest Service, Pacific Northwest Region, Portland, OR.

Richard S. Holthausen, Wildlife Ecologist, Terrestrial Team Co-Leader.USDA Forest Service, Washington Office, Corvallis, OR.

John F. Lehmkuhl, Wildlife Ecologist, Terrestrial Team Co-Leader.USDA Forest Service, Pacific Northwest Research Station, Wenatchee, WA.

Bruce G. Marcot, Wildlife Ecologist, Terrestrial Team Co-Leader.USDA Forest Service, Pacific Northwest Research Station, Portland, OR.

Wally Murphy, Wildlife Biologist.USDA Forest Service, Umatilla National Forest, Pendleton, OR.

Robert H. Naney, Wildlife Biologist, Vertebrates Group Leader.USDA Forest Service, Okanogan National Forest, Okanogan, WA.

Kurt Nelson, Wildlife Biologist, Terrestrial Team Co-Leader. USDA Forest Service, Payette National Forest, McCall, ID.

Dave Newhouse, Wildlife Biologist.USDA Forest Service, Intermountain Region, Ogden, UT.

Christine G. Niwa, Research Entomologist, Invertebrates Group Leader.USDA Forest Service, Pacific Northwest Research Station, Corvallis, OR.

Wayne Owen, Botanist.USDA Forest Service, Boise National Forest, Boise, ID.

Mike Pellant, Ecologist.USDI Bureau of Land Management, Idaho State Office, Boise, ID.

Martin G. Raphael, Research Wildlife Biologist, Terrestrial Team Co-Leader.USDA Forest Service, Pacific Northwest Research Station, Olympia, WA.

Terry Rich, Wildlife Biologist.USDI Bureau of Land Management, Idaho State Office, Boise, ID.

Roger Rosentreter, Botanist.USDI Bureau of Land Management, Idaho State Office, Boise, ID.

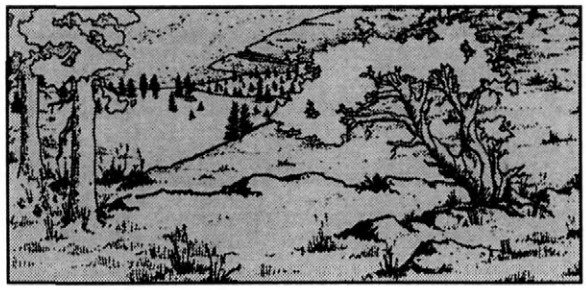
Vicki Saab, Wildlife Research Biologist.USDA Forest Service, Intermountain Research Station, Boise, ID.

Fred Samson, Wildlife Biologist.USDA Forest Service, Northern Region, Missoula, MT.

Roger E. Sandquist, Forester.USDA Forest Service, Pacific Northwest Region, Portland, OR.

J. Stephen Shelly, Regional Botanist.USDA Forest Service, Northern Region, Missoula, MT.

Karl Urban, Forest Botanist.USDA Forest Service, Umatilla National Forest, Pendleton, OR.



Barbara Wales, Wildlife Biologist/Data Base Manager.USDA Forest Service, Wallowa-Whitman National Forest, La Grande, OR.

Nancy Warren, Wildlife Biologist.USDA Forest Service, Flathead National Forest, Kalispell, MT.

Michael Wisdom, Wildlife Biologist.USDA Forest Service, Pacific Northwest Region, La Grande, OR.

Elaine Zieroth, Wildlife Biologist, Terrestrial Team Co-Leader.USDA Forest Service, Okanogan National Forest, Tonasket, WA.

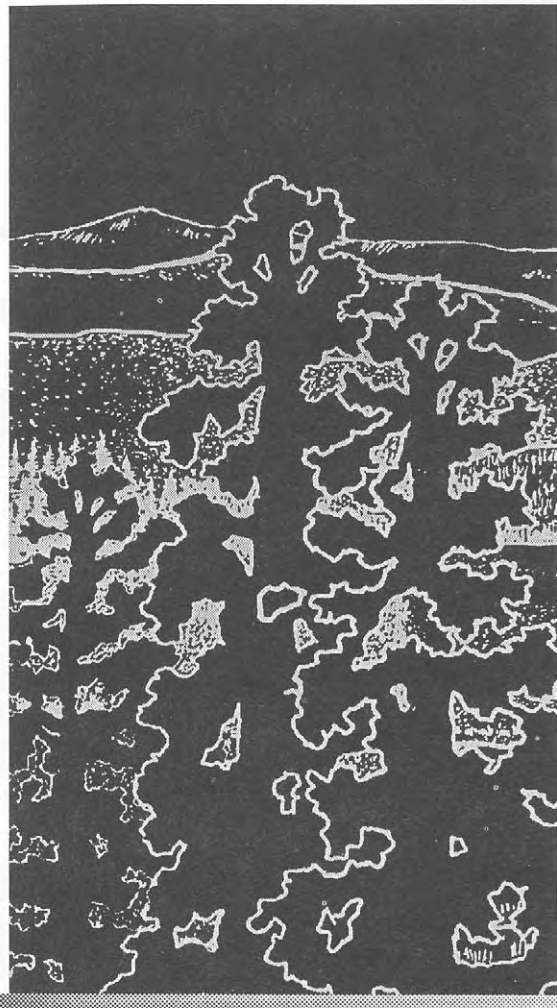
Acknowledgments



Literally hundreds of individuals have contributed to this publication. We thank all those who contributed to any portion of the overall Assessment effort. Individual chapters have included acknowledgments specific to that component of the Assessment. Editing and assembly of these chapters has been an enormous effort. Jodi Clifford, Liz Galli-Noble, Kathy Helm, Lynn Starr, Ann Marie Walker, Shari Whitwell, Lisa Meabon, Mary Carr, Ellen Eberhardt, Laurienne Riley, Tracy Noel, Cindy Dean, Heidi Bigler Cole, Kathy Campbell, Connie Gilbreath, Eloisa Munden, Dan Mayer, Minnie Williams, Kelly Wenzlick, Krista McHugh, and Berna MacIntosh have all contributed to this task. Irene Stumpf and Shari Whitwell created or edited many of the graphics. Traci McMerritt provided the cover design. Managing data, maps, tables, and databases for the Assessment was the specific responsibility of the Spatial Analysis Team: Becky Gravenmier, Terry Locke, Arthur Miller, Andy Wilson, Thang Lam, Dave Gilde, Mike Dana, Cary Lorimor, and Dora DeCoursey. Undoubtedly, we have failed to recognize many who made significant contributions to the Assessment, we apologize for any oversights.

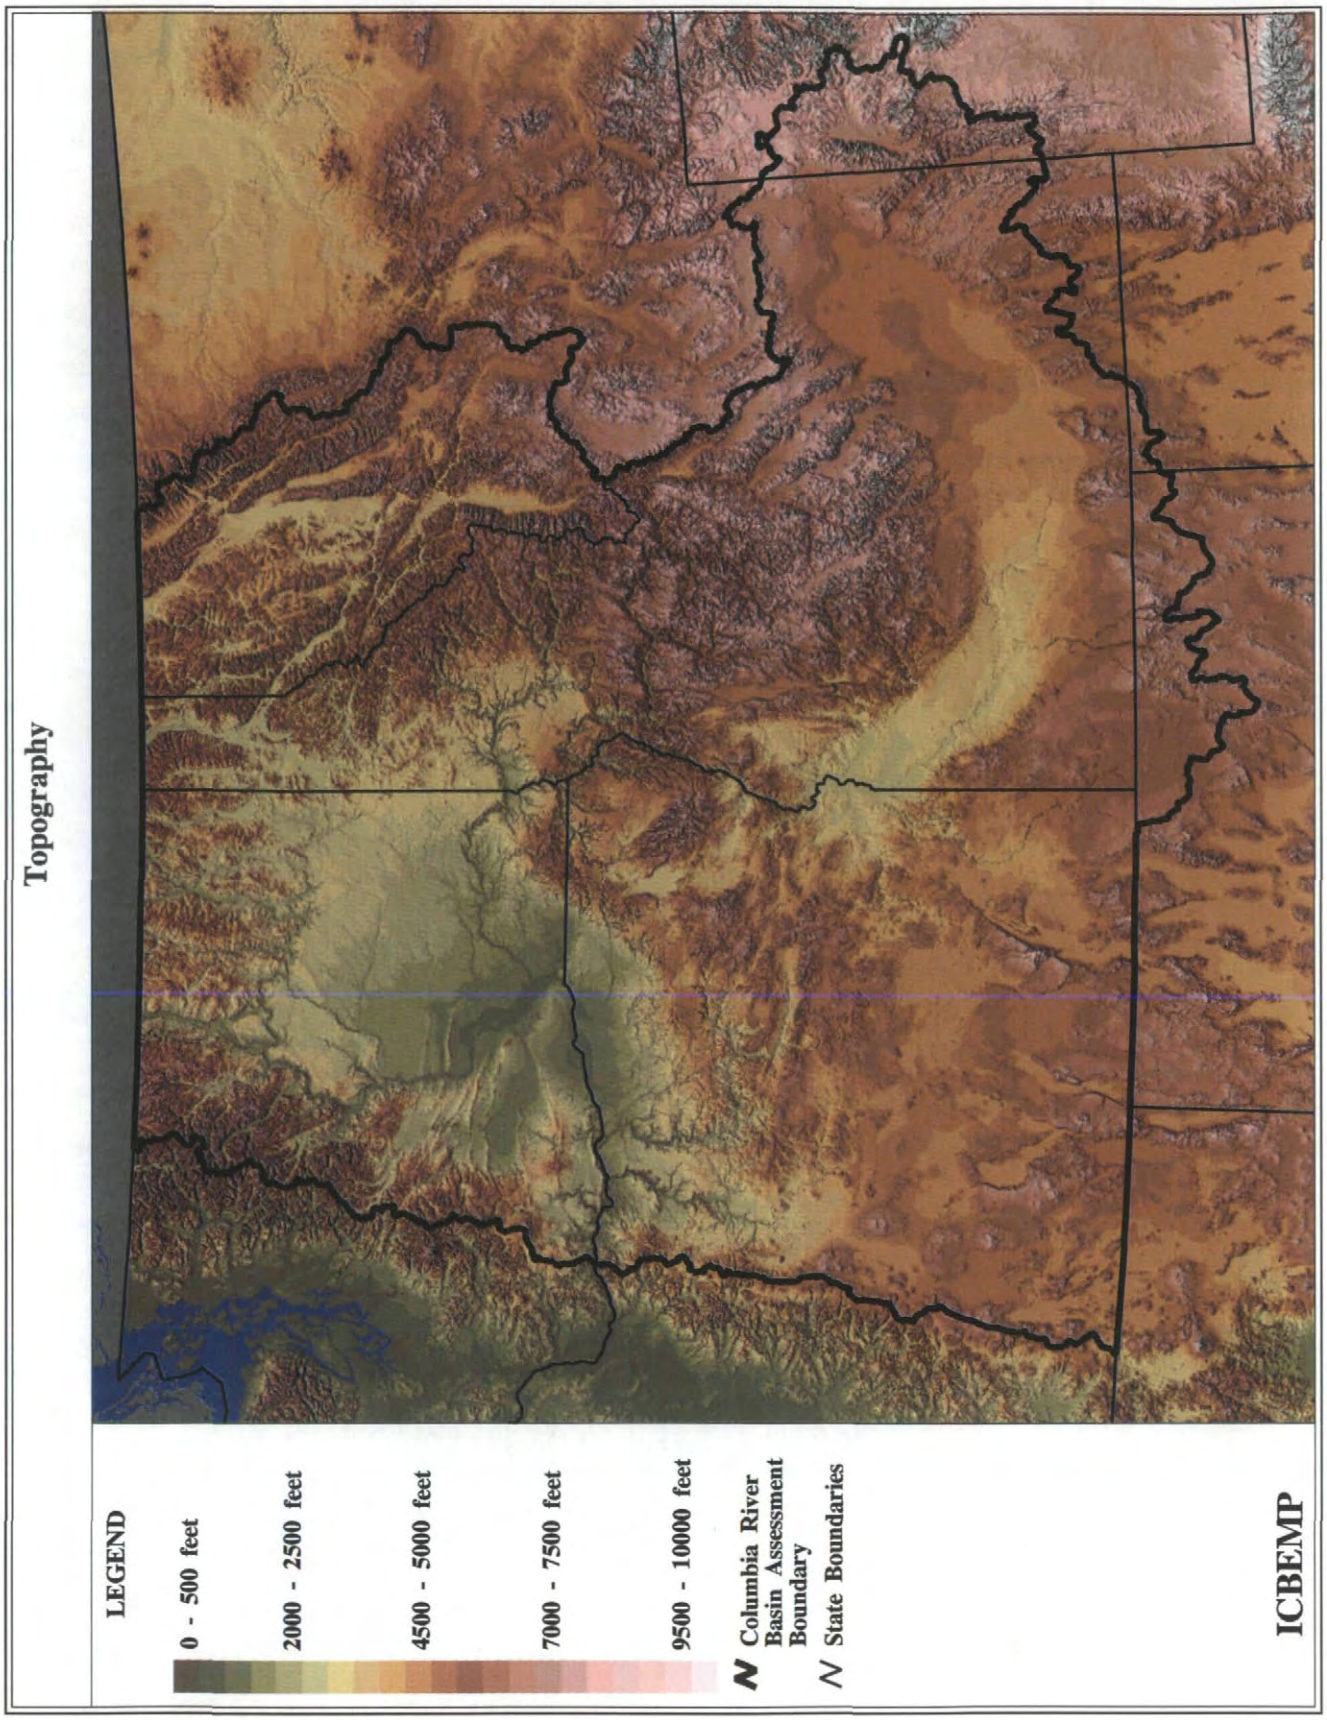
INTRODUCTION

The Pacific Northwest has been involved in controversy over the ownership, management, and disposal of natural resources since the descendants of Europeans began inhabiting the area 150 years ago. In recent decades, the debate over public land management has focused primarily on resource allocation, as commodity production took precedence over the custodial protection of national forest lands that characterized the early 20th century. In recent years concerns have grown about issues related to species associated with old forest structures, anadromous fish, forest health (including widespread insect and disease mortality and fire), and rangeland health. Appendix 1-A contains a chronology of recent, related events that reflect these concerns.



This assessment was precipitated by the current debate over the management of USDA Forest Service (FS) and USDI Bureau of Land Management (BLM) administered lands in those portions of the Columbia River basin within the United States and east of the Cascade crest and those portions of the Klamath and Great basins in Oregon. (This entire area is referred to as "the Basin" in this document.) To fully understand this debate and the implications associated with it, one needs to understand the biophysical, social, and economic components of ecosystems within the Basin. This assessment area includes Federal, State, county, and private resources. Such a broad examination provides information on conditions, trends, and potential outcomes associated with management of the Basin's natural resources.

The Interior Columbia Basin Ecosystem Management Project

President Clinton's 1993 Forest Conference held in Portland, Oregon, was designed to address forest management gridlock within the range of the northern spotted owl. A major outcome of the conference was the designation of the Forest Ecosystem Management Assessment Team (FEMAT). When announcing the completion of the FEMAT process, President Clinton directed the USDA Forest Service to take the lead in developing "a scientifically sound, ecosystem-based strategy" for managing the forests east of the Cascades.

The Interior Columbia Basin Ecosystem Management Project (ICBEMP) was established by the Eastside Ecosystem Management Project Charter (the Charter) in January 1994. The Charter was signed by the Chief of the Forest Service and the Director of the Bureau of Land Management. The charter provided instructions to develop specific products that would lead to the adoption of a scientifically sound, ecosystem-based strategy for managing FS- or BLM-administered lands within the Basin. Information necessary to develop the strategy required assessing a large portion of the inland northwest (map 1.1).

The total assessment area of the Basin is 58.4 million hectares (ha), 30.9 million ha of which are administered by 35 national forests and 17 BLM districts (tables 1.1 and 1.2). The remaining area is shared among other Federal, State, county, and

Map 1.1—Columbia River Basin of the United States and portions of the Klamath River Basin and the Great Basin that will be assessed in developing an ecosystem approach for managing public land administered by the Forest Service and Bureau of Land Management in the Interior Northwest.

Table 1.1— Ownership of lands within the Basin assessment area.

Ownership	Lands		
	-----Acres-----	---Hectares---	--Percent--
BLM- or FS-administered lands	76,274,273	30,867,100	53
Other Wilderness and National Parks	1,599,761	647,400	1
Private and other lands	54,666,141	22,122,600	38
State and other Federal lands	6,236,940	2,524,000	4
Tribal lands	5,437,061	2,200,300	4
Basin total	144,214,176	58,361,400	100

Note: Areas generated from 1 sq. kilometer grid using Geographic Information System. Totals will not match official Government Land Office totals.

Table 1.2— Land ownership, by Ecological Reporting Unit for the Basin assessment area.

	Ownership/Administration					
ERU	FS/BLM	Other Wilderness/ National Parks	Private	State/ other Federal	Tribal	Total land area
	hectares					
1. Northern Cascades	1,399,800	54,100	609,300	181,300	296,800	2,541,300
2. Southern Cascades	768,700	0	440,300	20,200	126,200	1,355,400
3. Upper Klamath	737,700	31,300	786,600	11,800	0	1,567,400
4. Northern Great Basin	3,160,300	0	782,500	240,300	7,200	4,190,300
5. Columbia Plateau	1,053,600	800	7,514,700	674,900	282,600	9,526,600
6. Blue Mountains	2,667,900	0	2,378,100	35,200	600	5,081,800
7. Northern Glac. Mtns	2,734,200	256,400	2,500,800	294,000	1,155,200	6,940,600
8. Lower Clark Fork	1,782,000	0	803,000	120,100	3,400	2,708,500
9. Upper Clark Fork	1,238,100	0	1,033,900	19,800	1,900	2,293,700
10. Owyhee Uplands	5,452,500	0	2,002,200	355,300	117,000	7,927,000
11. Upper Snake	1,427,700	21,400	1,483,800	275,000	185,000	3,392,900
12. Snake Headwaters	1,635,400	283,200	639,100	55,400	24,400	2,637,500
13. Central Idaho Mtns	6,809,200	200	1,148,300	240,700	0	8,198,400
Basin total	30,867,100	647,400	22,122,600	2,524,000	2,200,300	58,361,400

(Source: Basin GIS data, converted to 1 sq. kilometer raster data)

tribal governments and private land owners. The combined land managed by the BLM and the FS is about 53 percent of the total assessment area. Data were collected from an area somewhat larger than the assessment area to assist in landscape characterizations (Landscape Characterization Boundary, map 1.2).

The Charter provided guidance on the structure and organization of the overall project (fig. 1.1). An interagency approach to natural resource issues was used because such an approach recognizes the multiple geographic extents, the complexity of resources and issues, and the multiple jurisdictions within the Basin. To provide direction and oversight, the Columbia Basin Executive Steering Committee was established. The committee consists of the Regional Foresters from Forest Service Regions 1, 4, and 6; the Directors of the Forest Service Pacific Northwest Research Station and the Intermountain Research Station; and the BLM Directors from Oregon-Washington, Idaho, and Montana.

The Charter provided direction for the completion of a framework for ecosystem management and a scientific assessment of the Basin (table 1.3). The document, *A Framework for Ecosystem Management in the Interior Columbia Basin and Portions of the Klamath and Great Basins (Framework)* (Haynes and others 1996), describes the principles and planning and analysis processes applicable for managing ecosystems in the Basin at multiple geographic extents and resolutions of data. The scientific assessment of the Basin (ICBEMP Assessment), of which this document is a part, examines the status of ecosystems within the Basin including their historic trends, current status and trends, and projections about their future outcomes and conditions.

The Charter also required the preparation of two Environmental Impact Statements (EISs), one for the Upper Columbia River Basin (UCRB) and one for eastern Oregon and Washington (EEIS), and the scientific evaluation of the EIS alternatives. The draft EISs present seven alternative management strategies based on ecosystem management concepts intended to provide long-term direction for agency lands within the assessment area. The scientific evaluation of EIS alternatives analyzes the effects of implementing each alternative management strategy. The Executive Steering Committee plans to adopt an ecosystem management strategy for managing FS- and BLM-administered lands in the Basin after completion of the EISs.

The Science Integration Team (SIT) was established to develop the *Framework*, the Scientific Assessment of the Basin, and an evaluation of EIS alternatives. The EISs were prepared by other teams.

Major policy questions summarized from the Charter represent the minimum questions the Executive Steering Committee viewed as essential to address through the assessment/decision processes of the project (table 1.4). The policy questions include concerns about outcomes of current levels of activities on ecologic and human systems, maintenance of long-term productivity, mimicking disturbance on the landscape, sustainability, biological diversity, rural communities, old-growth ecosystems, forest health, adaptive management, and endangered and other species viability. In the Assessment, the SIT provided information needed by the EIS teams to address policy questions and other issues brought forward through the EIS process.

The SIT was organized around the functional staff areas of landscape ecology (physical and vegetative resources), terrestrial resources, aquatic resources, economics, and social sciences. A staff of Geographic Information System (GIS) specialists supported the spatial and data processing needs of the functional groups. The SIT was composed of Federal employees from the FS, BLM, Environmental Protection Agency (EPA), U.S. Geological Survey (USGS), and Bureau of Mines (USBM). Contractors were brought in for specific tasks and assignments. SIT headquarters were in Walla Walla, Washington. Detached analysis units were located in Missoula and Kalispell, Montana; Boise, Moscow, and Coeur d'Alene, Idaho; Portland and Corvallis, Oregon; Seattle, Spokane, and Wenatchee, Washington; and Reno and Las Vegas, Nevada.

Map 1.2—Landscape Characterization Boundary.

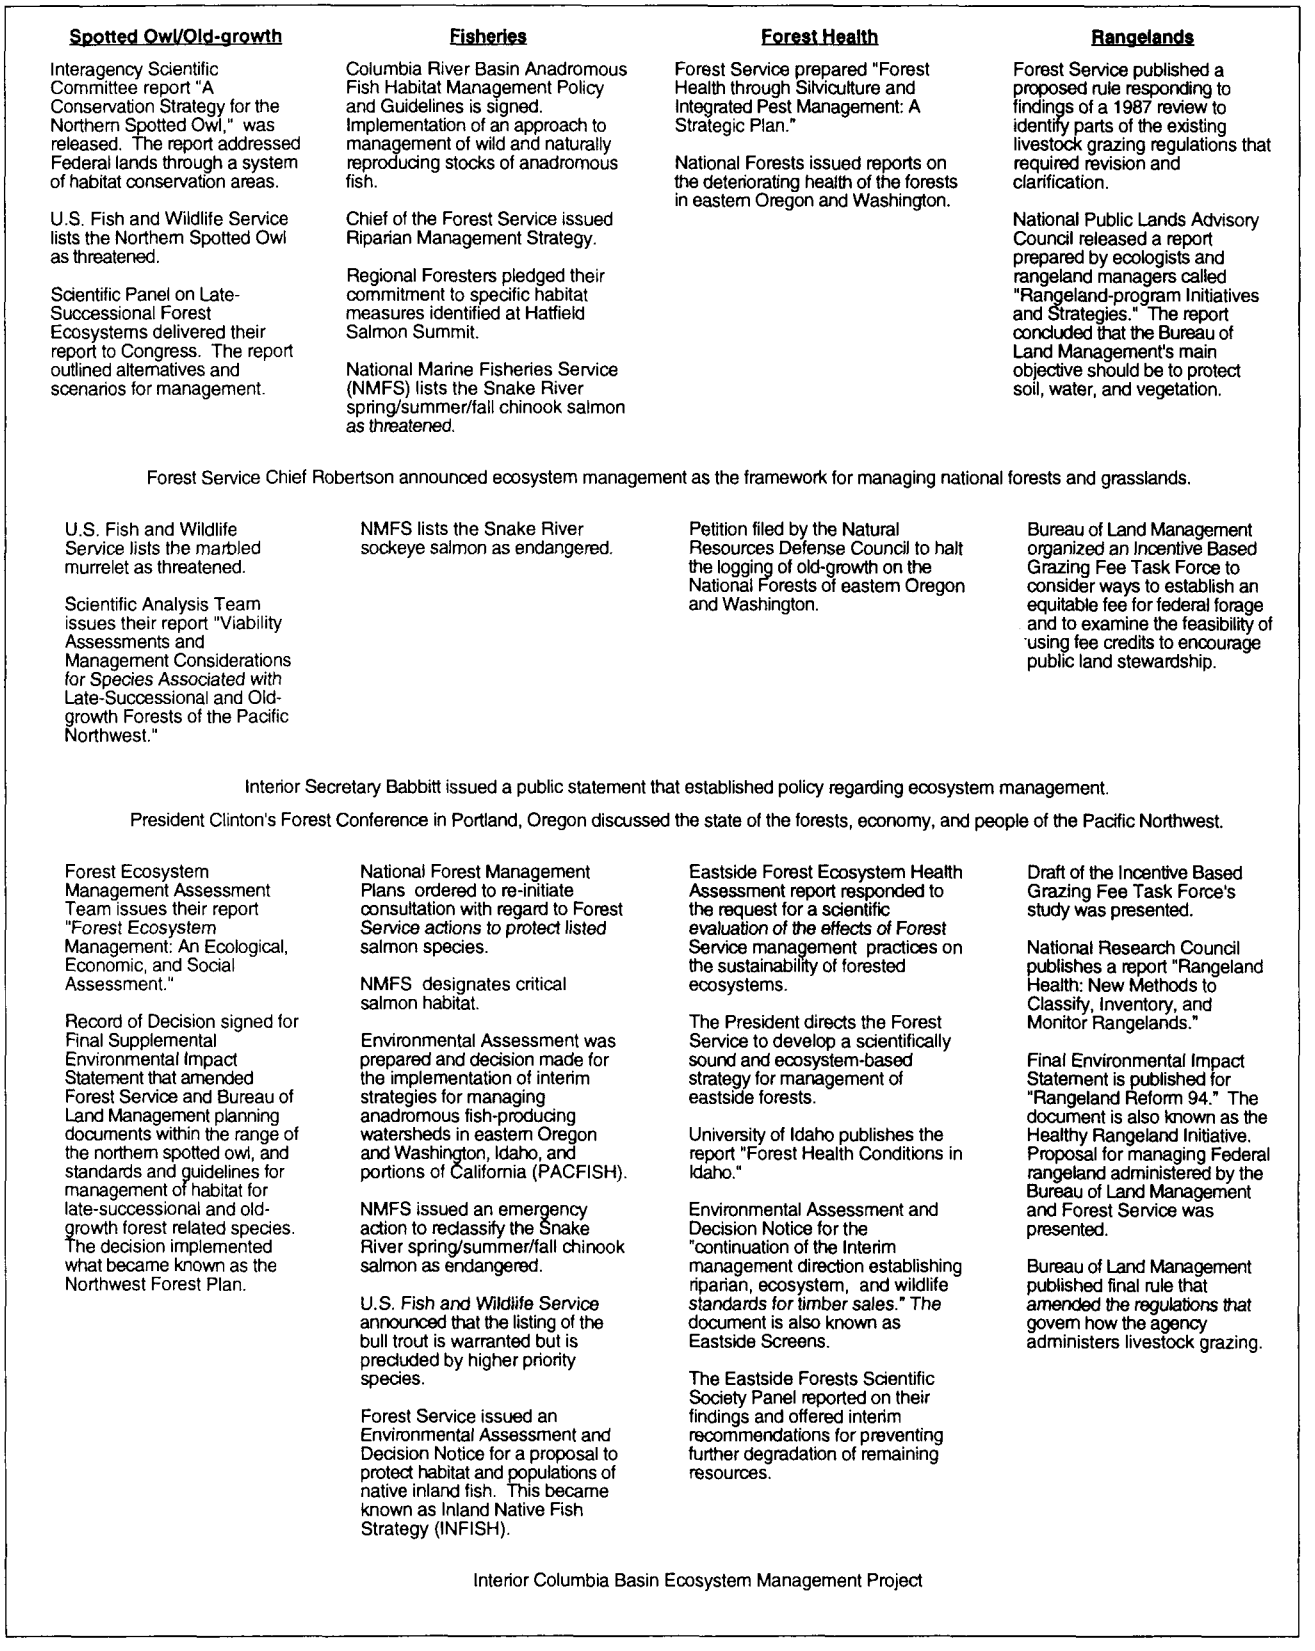

Figure 1.1—Issues and events that led to the Interior Columbia Basin Ecosystem Management Project.

Table 1.3— Major products expected from the Interior Columbia Basin Ecosystem Management Project.

Product	Responsible Team	Description
Scientific Assessment	Science Integration Team	Assessment of the historic, current, and potential future status and trend for terrestrial, aquatic, landscape ecology, economic, and social systems in the Basin
Framework	Science Integration Team	Description of the principles and processes appropriate for managing ecosystems within the Basin
Eastside EIS	Eastside EIS Team	Proposal of new goals, objectives, standards, and guidelines applicable to national forests and BLM districts in eastern Oregon and Washington
Upper Columbia River Basin (UCRB) EIS	UCRB EIS Team	Proposal of new goals, objectives, standards, and guidelines applicable to national forests and BLM districts in the UCRB
Evaluation of Alternatives	Science Integration Team	Evaluation of EIS alternatives that discloses outcomes, tradeoffs, consequences, and relative risks to ecological integrity and economic resiliency

The ICBEMP Scientific Assessment

The ICBEMP Scientific Assessment provides information about current conditions and trends. The information can be used by land managers to develop broad land management goals and priorities. It also provides the context for decisions specific to smaller geographic areas. The objectives of the assessment are to:

- Characterize and describe the conditions of the landscape ecology, aquatic/riparian, terrestrial, social, economic, and landscape conditions of the Basin. These characterizations describe the present conditions of the Basin, the historic conditions, their evolution, and the likely future of the Basin under different scenarios.
- Provide information that can be used to implement ecosystem management at different geographic scales within the Basin. The assessment provides information that local land managers can use to put decisions and management practices into a larger geographic context. It also provides information that the regional land manager can use to define processes or structures that may be important for maintaining ecosystems and supplying goods and services. In addition, the assessment supplies information that can address the issue of ecosystem integrity for various geographic areas within the Basin and for the Basin as a whole.
- Identify information gaps that need to be addressed through research and development. Implementing ecosystem management strategies allows flexibility based on local assessments of the area's conditions and trends as the concept of ecosystem management evolves.

Table 1.4— Policy questions identified from the Charter.

Major Policy Questions
What are the effects of current and potential Forest Service and Bureau of Land Management land allocations on ecologic, economic, and social systems in the Basin?
What are the ecologic, economic, and social system outcomes associated with current (early 1990s) Forest Service and Bureau of Land Management levels of activities?
What is required to maintain long-term productivity (in terms of various systems)?
What can the Forest Service and Bureau of Land Management do to mimic disturbance elements on the landscape?
What is required to maintain sustainable and/or harvestable and/or minimum viable population levels?
What is required to maintain and restore biological diversity (biodiversity)?
What is the impact of ecosystem management on major social issues and the maintenance of rural communities and economies?
What is the impact of ecosystem management on maintenance of late-successional and old-growth systems?
What management actions will restore and maintain ecosystem health (forest, rangeland, riparian, and aquatic health)?
What can the Forest Service and the Bureau of Land Management do to implement adaptive management and what are its consequences on ecologic, economic, and social systems in the Basin?
What can the Forest Service and Bureau of Land Management do to protect endangered species (such as salmon, grizzly bear, gray wolf, caribou) and ensure the viability of native and desired non-native plant and animal species?
Effects of Specific Policy Actions
Within the context of the President's Northwest Forest Plan, what are the options for achieving the objectives where the President's Plan overlaps the Eastside strategies?
What is the effect of implementing the interim direction of the Pacific Anadromous Fish Strategy and/or other proposed aquatic conservation strategies on Forest Service and Bureau of Land Management administered lands in the Basin?
Process Questions
What are the principles and processes that can be used for ecosystem management?
How can we use the assessment to identify emerging policy issues that relate to ecosystem management within the Basin?
How can we deal with uncertainty in ecological processes, social values, predicting outcomes, and scientific understanding?

The ICBEMP Scientific Assessment used information from many sources and disciplines and on all lands within the Basin, not just FS- and BLM-administered lands. Understanding ecosystem components, structures, processes, and functions that operate at multiple geographic and temporal extents and providing context for decisions requires that all lands be included in the assessment. While respecting the rights of landowners within the Basin, information was gathered from both public and private sources. Because of the broad level of data resolution used in the assessment and the large geographic extent, the assessment relied primarily on remote sensing or readily available information from third party sources. An effort was made to use the existing information about the past and present condition of the Basin. To the extent possible, the SIT relied on existing simulation models to project future conditions of the Basin. Where existing models were not available, new models were constructed. Inferences about future conditions were made from the available information and the model results.

The ICBEMP Scientific Assessment has resulted in the preparation of several major documents. It also generated many smaller documents and a number of databases and models. The databases contain information on vegetation, landform, climate, stream inventories, terrestrial species relationships, county indicators and economic conditions. The models range from those that predict change in vegetation under different disturbance regimes to those that describe community resiliency.

Database/information systems/information gathering for this project can be generally categorized into five basic groups: 1) databases (more than 20 were acquired or developed, 2) GIS themes (over 170 were generated), 3) expert panels/workshops (about 40 were convened), 4) contract reports (over 130 were used), and 5) current literature reviews. A list of databases and GIS themes are included in the chapter titled Information System Development and Documentation.

This document is an *Assessment of Ecosystem Components*, composed of detailed reports from each functional staff area. It addresses the biophysical and social conditions of the Basin. Another document, *An Integrated Scientific Assessment for Ecosystem Management for the Interior Columbia Basin and portions of the Klamath and Great Basins* (Quigley and others 1996) integrates the information presented here and discusses current conditions. The Integrated Assessment also examines the extent of ecological risk and departure from historical and potential vegetation conditions. This is accomplished by integrity indices and probable outcomes of management under various possible futures. In support of these documents, and as background to the conclusions, other technical reports will be published in the future. More detailed explanations of databases, models, and information layers will be useful to both public and private land managers.

Unlike previous efforts where public involvement occurred only when mandated under the National Environmental Policy Act (NEPA), the ICBEMP encouraged public participation during all phases of the project. Members of the public were encouraged to attend workshops and regularly scheduled public meetings. Reports from contractors and other draft materials were readily available. For example, the Project provided a local printing/copying service with copies of draft project reports so that the public could obtain their own copy. Much of the material was accessible through an electronic library maintained by project personnel. Finalized data layers and maps were available to the public. Although this approach required a commitment of both personnel and financial resources from the SIT, it helped remove the potential for surprise and helped SIT members better understand public expectations.

The scientific documents developed by the SIT were subjected to peer review using a modified double-blind process. A science review board (SRB) was formed comprising six members and two co-chairs. The SRB independently chose reviewers from a list of knowledgeable scientists,

land managers, and regulatory personnel. This ensured an impartial but informed review process. Products of the SIT were received by the SRB co-chairs and forwarded to other SRB members for assignment to outside reviewers for diverse points of view. These reviews were sent to SIT without integration, attempts at consensus, or accompanying advice.

Scale, Geographic Extent, and Data Resolution

Following the classification system presented in the *Framework*, the Basin assessment includes elements of both a regional and sub-regional assessment. This approach was undertaken because several of the policy questions and issues could not be adequately addressed using a regional assessment alone. This approach also provided consistency across geographic areas as well as the context for decisions specific to a landscape or a watershed.

The degree of data resolution sought for each component of the analysis (landscape ecology, aquatic, terrestrial, economic, and social) was determined by the policy questions. Current vegetation cover and structure were mapped using a continuous one-square-kilometer (1 km^2) resolution, which relied on satellite images and validation workshops with field ecologists. Potential vegetation was mapped at 1-km^2 resolution using biophysical characteristics and existing field data. Other map themes characterized the broad, regional environment.

To gain insight into the variability in disturbance processes, vegetation patterns, and vegetation structure within the Basin, sampling was done at the mid, sub-regional assessment level. Comparisons were made between recent (1920-1945) and current vegetation characteristics measured through aerial photography interpretation on 335 sub-watersheds within the Basin. This mid, sub-regional assessment data provided information relating to insect and disease attributes, shifts in cover types and structural stages, and changes in fire regimes. Combined, the broad, regional and mid, sub-regional information provided the basis for interpretation of habitat changes, aquatic interactions, disturbance processes, and human interactions.

In landscape ecology terms, there is often referral to broad-scale information and mid-scale information. In this context, the broad scale refers to information with the lowest degree of resolution, similar to classifying landscape patterns from a photograph taken from five miles above the earth's surface. Mid-scale refers to information with more resolution, similar to classifying landscape patterns from a photograph taken from one mile above the earth's surface.

The social and economic information used in this Assessment was generally at the state and county level of aggregation. Communities within the Basin were sampled to determine basic characteristics and the degree to which the communities could absorb change without major disruptions within their social/economic systems. Bureau of Economic Analysis reporting areas were used to characterize centers of trade and economic activity. These represent groupings of several counties per analysis area (map 1.3).

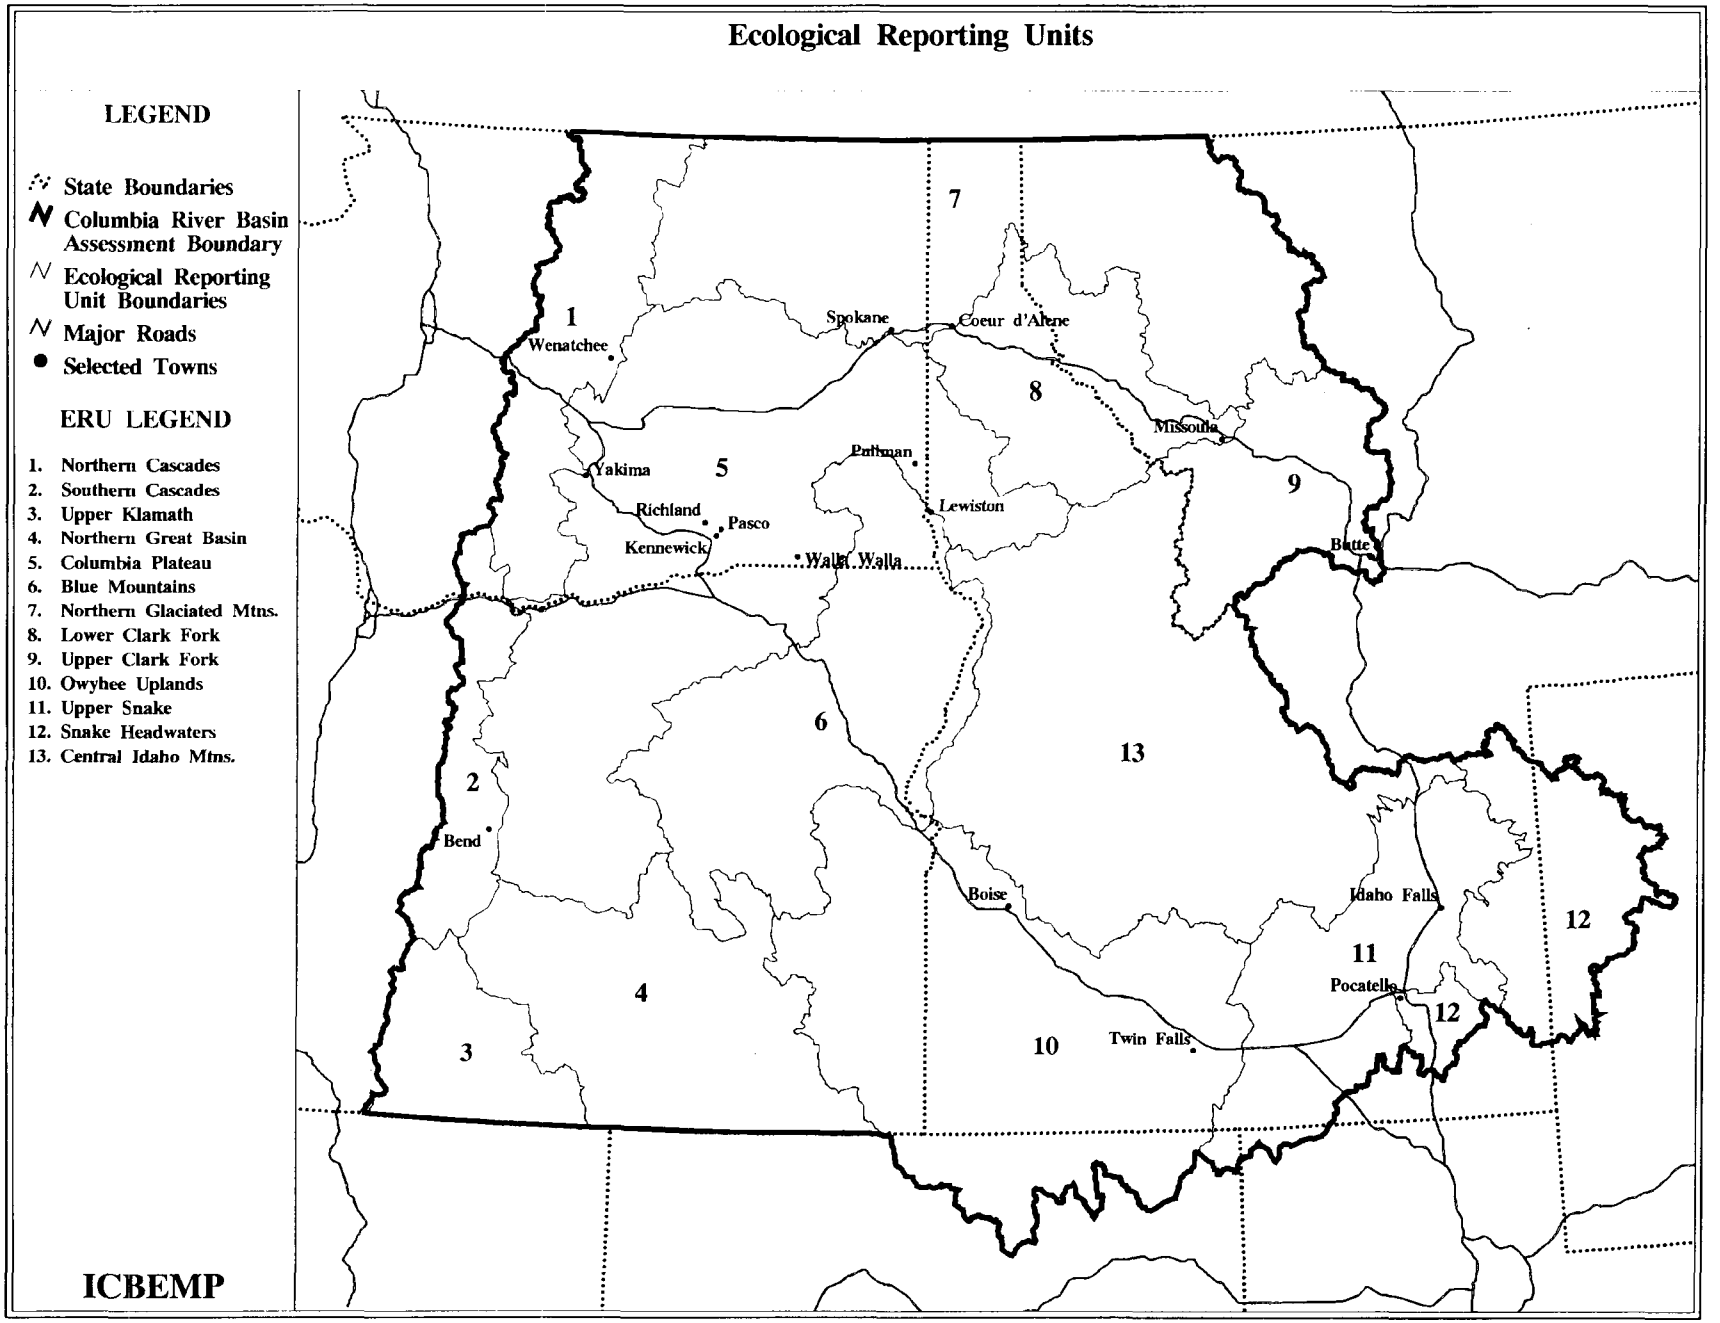
Use of Ecosystem Principles and Concepts in the ICBEMP Assessment

To paraphrase Salwasser and others (1993), ecosystems can be defined as communities of organisms interacting with their environments as integrated units. They are places where all plants, animals, soils, waters, climate, people, and processes of life interact as a whole. Because humans have developed the capacity to rapidly alter the environment and because humans are dependent, like all species, on the environment, humans are included in this Assessment as a component of ecosystems.

Several broad ecosystem principles and concepts guided the work for the Assessment and are briefly discussed below. For a more complete discussion of ecological principles and concepts, see the *Framework* or the Biophysical Environments chapter of this document. First, ecosystems are dynamic, evolutionary, and resilient. Change is

Map 1.3—Economic Analysis Areas of the interior Columbia Basin.

inherent, which allows ecosystems to develop along many paths (O'Neill and others 1986; Urban and others 1987). Second, ecosystems are viewed spatially and temporally within multiple organizational levels. These levels can be organized within a hierarchy in which every level has discrete ecological functions but also is part of a larger whole (Allen and others 1984; Allen and Starr 1982; Koestler 1967), although terrestrial, aquatic, economic, and social systems may operate within different hierarchies. In the Assessment, the landscape ecology, aquatic, terrestrial, economic, and social elements are discussed in the hierarchies that are determined to be most appropriate for each. Third, ecosystems have biophysical, economic, and social limits. Fourth, ecosystem patterns and processes are not completely predictable although predictability varies over temporal and spatial organizational levels (Bourgeron and Jensen 1994).



Ecological integrity, the degree to which all components of a system and their interactions are represented and functioning, is an important concept. An ecosystem is resilient when it returns to some constant state after change or disturbance or when it cycles within some definable bounds (Hilborn and Walters 1992). In the social and economic sense, resiliency is the capacity of a system or community to confront and adapt to change.

In the Assessment, the SIT looked at historical conditions and the dynamic processes at work on the landscape that have led to the current conditions. Although the SIT did not state threshold values or definite limits for system components, sufficient information is presented on current conditions and trends for the reader to understand where the greatest amount of departure from historic conditions has occurred. Discussions about ecological integrity and socioeconomic resiliency are presented in both this document and in the *Integrated Scientific Assessment.*

The *Framework* describes how assessments, risks, and decisions relate at multiple levels. Risks are defined as activities or events that pertain to the likelihood of not reaching desired goals. Uncertainty refers to the type of events that dominate ecosystem change where outcomes cannot be predicted in probabilistic terms. This Assessment is aimed at understanding the relations among events, activities, outcomes, and opportunities. Thus, it is an essential step in the cycle of risk management.

Ecological Reporting Units and Ecosystem Modeling

To facilitate the analysis and presentation of information and results on areas smaller than the entire Basin, the Basin was divided into 13 geographic areas called Ecological Reporting Units (ERUs). ERUs were defined by the landscape ecology, terrestrial, and aquatics staff of the SIT. Proposed ERU boundaries from the terrestrial team were based primarily on the section delineations from "Ecological Subregions of the United States: Section Descriptions" (McNab and Avers 1994) and subsection delineations produced through the ICBEMP. The section/subsection boundaries were adjusted to the nearest sixth (6th) field hydrologic unit boundary, or subwatershed that ranges in size from 12,350 acres to 49,400 acres. Boundaries proposed by the aquatics staff emphasized aquatic ecosystem components and were based primarily on groupings of fourth (4th) field hydrologic units, or watersheds that range in size from 98,800 to 617,500 acres. These 4th-field groupings contained similar hydrologic characteristics that were identified through cluster and discriminant analysis of watershed characteristics and stream-gauging station data. This strategy also incorporated general data about the distribution of aquatic species and zoogeographic data. These approaches yielded similar delineations and were combined using 6th-field hydrologic units as the basic mapping unit to create the ERUs (map 1.4).

Map 1.4—Ecological Reporting Units.

To the extent possible, the ERUs provided the basis for the descriptions of biophysical environments, the characterization of ecological processes, the discussion of the effects of land management activities and observed trends from past management, and the discussion of the complexities of managing landscapes in the future. However, some ecological processes and functions do not conform well to the ERU boundaries. Where this occurred, the assessment used a more appropriate context. For some topics, lack of detailed information resulted in evaluating the entire Basin and not smaller units.

Scenarios

The *Integrated Scientific Assessment* brings together a discussion of interactions and outcomes associated with possible futures. A scenario is a description of a possible course of action and its probable outcomes. Scenarios can be used to improve the understanding of possible outcomes of various actions or policies. Unlike EIS alternatives, they need not be designed to achieve a particular purpose but may be used to explore key factors in how systems operate. Scenarios can also be very broad and encompass changes that are beyond the authority of a specific decision-maker in the Basin. Scenarios were used in this project to test analytical models, predict possible trends in conditions on lands within the Basin, and facilitate the development of EIS alternatives by providing insights into outcomes associated with a wide range of futures. Four scenarios were developed, each of which emphasized a different type of management. They are broadly described as: 1) continuation of current management, 2) emphasis on commodity production, 3) passive management of ecological processes, and 4) active management of ecosystem functions and processes. These scenarios provided background for the development of the EIS alternatives and initial model parameters for simulating futures. The *Integrated Scientific Assessment* contains discussions of assumed societal goals, management options inferred by those goals, and ecological integrity of expected outcomes. Some discussion of scenario outcomes can be found in the following chapters as well.

Overview of the Basin

The lands in the Basin are highly diverse. They range from the Cascade crest in the west to the Continental Divide in the Rocky Mountains on the northeast and east. The Bitterroot, Selkirk, Cabinet, Salmon River, Lemhi, and Purcell mountain ranges in central Idaho and western Montana commonly have elevations over 3,000 meters. The Basin also encompasses the extensive basalt plateau of eastern Oregon, eastern Washington, and southern Idaho as well the high desert of the Klamath Basin in southwest Oregon and the plains of the Great Basin in northern Nevada, northern Utah, and southern Idaho.

Events during the Pleistocene epoch shaped much of the Basin's landscapes. Lobes of the ice sheet originating in Canada excavated and molded valleys in the northern portion of the Basin while alpine glaciers occurred in most of the mountainous areas. Many large lakes formed as a result of the wetter climate, particularly in southern portions of the assessment area where closed basins exist. Repeated breaching of ice dams by glacial Lake Missoula led to cataclysmic flooding that carved the "channeled scablands" of eastern Washington. Spillover of pluvial Lake Bonneville into the Snake River system modified the valley of the Snake River and left large cataract complexes. Sedimentary deposits including glacial till, outwash, and loess, and valley fill, terraces, and scour features occur over much of the Basin. Soils developed from loess deposits in the Columbia Plateau and Snake River plain have enabled these areas to develop into highly productive agricultural areas.

The Basin is in a transition-type climate zone, and climate patterns are dominated by topographic features. Type and distribution of vegetation varies depending on the soils, long-term precipitation patterns, and climate. Forested vegetation varies among the dry, moist, and cold potential vegetation types. Dry forest potential vegetation is typical on lower elevation sites with low levels of precipitation and is generally more dominant in the western and southern portions of the Basin. Moist forest

potential vegetation is typical of mid-elevation areas with higher levels of precipitation. These areas are more typical of the northern and central areas of the Basin. Cold forest types are typical of higher elevation areas, such as along the Continental Divide. Grassland, shrubland, and woodlands are also present across the Basin. These vary between desert (very dry) areas and high elevation (very cold) areas.

Most of the area is drained by the Columbia River and its tributaries. The portion of the Klamath Basin that occurs in the project area is drained by the Klamath River and its tributaries; the portion of the Great Basin within the project area has closed basins. Stream modifications to facilitate navigation on the Columbia River system began in 1876 with the construction of locks and canals. By 1975, the waterway between Lewiston, Idaho, and the Pacific Ocean had become a series of reservoirs. This dam system provides 40 percent of the Nation's hydropower production, navigation and irrigation benefits, flood control, and recreational opportunities. Irrigation from both surface and ground water sources is by far the dominant off-stream use of water in the Basin.

The Basin covers about 8 percent of the U.S. land area and contains about 1.2 percent of the Nation's population. This results in a population density that is less than one-sixth of the U.S. average. The area has experienced recent, rapid population growth. Thirty-one percent of the Basin's population lives in urban areas in contrast with the rest of the nation where 77.5 percent of the population lives in urban areas. The racial and ethnic composition of the Basin is also quite different from the rest of the country. Generally, the Basin has a higher percentage of Caucasians; a greater proportion of American Indians; and a smaller proportion of African-Americans, Hispanics, and Asians than the United States in general.

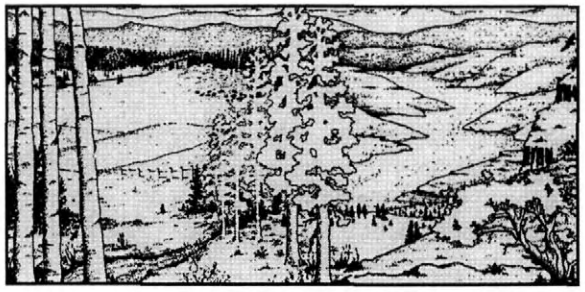
The Basin covers about 24 percent of the Nation's National Forest System lands and 10 percent of the Nation's BLM-administered lands. Designated wilderness within the Basin accounts for 29 percent of the wilderness acres within the contiguous United States. The relatively large amount of Federal land and designated wilderness in the Basin is one of the reasons why available recreation resources are greater than the national average. The relative rate of participation in outdoor recreation is significantly higher than in other regions of the Nation.

The Basin has a diverse economy which composes 3.6 percent of the U.S. economy. Six metropolitan counties have been the center of its economic growth. Spokane, Boise, Richland/Pascoe/Kennewick ("Tri-Cities"), Yakima, Bend, and Wenatchee are the major urban areas in the Basin. The past two decades have seen the evolution of what was a mature, resource-based economy into a diverse economy oriented toward the technology, transportation, and service sectors. Economic strengths of the Basin include agriculture and agricultural services.

Chapter Organization And Development

The Scientific Assessment provides information about current conditions and trends within the Basin that can be used by land managers to develop broad land management goals and priorities and that provides the context for decisions specific to smaller geographic areas. This document, composed of detailed reports from each functional staff area, addresses the biophysical and social conditions of the Basin.

Each of the functional staff areas developed approaches that best suited an examination of the resource and policy questions related to their specific area of study. The following chapters reflect that variation in approach. All of the chapters discuss study methodologies and results but contain varying amounts of discussion related to ERUs, scenarios, and ecosystem integrity. The amount of detail also varies between chapters. Summaries for all chapters are located immediately following this section.



Chapters 2 and 3 contain information on the ecology of the Basin's landscapes. Chapter 2 presents a discussion of biophysical environments including multi-scale descriptions of geologic, climatic, geoclimatic, potential vegetation, soils, and hydrologic system organization. The hydrologic integrity for 12 forest and range clusters is also discussed. Chapter 3 discusses multi-scale landscape dynamics including processes of change; changes in vegetation, cover types and patterns; and forest and range conditions.

Aquatic and terrestrial species and habitats are discussed in Chapters 4 and 5. Chapter 4, Broadscale Assessment of Aquatic Species and Habitats, includes descriptions of the primary elements of change that affect the integrity of aquatic ecosystems; the relation between small-scale stream features, landscape-scale features, and human activities; the distribution and status of fishes in the Basin; and ecological opportunities and risks. Chapter 5 contains information on the terrestrial ecology of the Basin including distribution of species, species habitats, and key environmental correlates. Viability projections for both aquatic and terrestrial species that may be associated with various management alternatives are not included in this document.

Socioeconomic information is presented in Chapters 6 and 7. The Economic Assessment includes discussions of regional economies, economic efficiency, and equity. Economic issues related to particular resources managed by the FS and BLM including fish, minerals, range, recreation, special forest and range products, timber, and water are analyzed. The importance the BLM and FS lands to the economies of the Basin is also explored. The Social Assessment includes information on history; population demographics; attitudes, beliefs, and values of various segments of society; communities and lifestyles; the role of public land amenities; public participation; and institutional issues. The chapter also provides information on American Indians and the trust responsibilities of the Federal Government.

Information System Development and Documentation for the assessment is presented in Chapter 8. This chapter describes how the data collected for the assessment were managed using Geographic Information Systems (GIS), conventional databases, and other electronic tools.

Other technical reports will be published in the future. Such reports may include those that were completed in preparation for this assessment, those that contain more detailed information not included in these chapters, and those that may be completed by researchers using information gathered for this project, but not yet fully analyzed. More detailed explanations of databases, models, and information layers will be useful to both public and private land managers. Documentation of data themes and GIS layers are available as part of the administrative record for this project.

ACKNOWLEDGMENTS

The preparation of this introductory chapter has involved several people. The authors would like to thank Lynn Starr and Mary Keith for their valuable input and review, Ken Brewer for the description of the process used to delineate Ecological Reporting Units, Cindy Dean for her chronology of recent events, Becky Gravenmier and the spatial team for the maps and spatial information, Irene Stumpf for the graphics, and Jodi Clifford for editing and general document coordination.

GLOSSARY

adaptive management - Feedback which consists of knowledge or data on the effects or results of an action. Information is purposely collected and used to improve future management actions.[1]

biodiversity (biological diversity) - The diversity of plant and animal communities, including endemic and desirable naturalized plant and animal species.

biomass - The total mass of living matter within a given volume of environment.[2]

biome - An entire community of living organisms in a single major ecological region.[2]

biophysical - The combination of biological and physical components in an ecosystem.

biotic - Living; relating to life or specific life conditions.[2]

decision-maker - In the use of federal land management, the person authorized to make land management decisions.

desired future condition - A portrayal of the land or resource conditions that are expected to result if goals and objectives are fully achieved (36 CFR 219).

disturbance - Any event that alters the structure, composition, or function of terrestrial or aquatic habitats; fire, flood, and timber harvest are examples of large-scale disturbance.

disturbance regime - Natural pattern of periodic disturbances, such as fire or flood, followed by a period of recovery from the disturbance. Such as regrowth of a forest after fire.

diversity - The distribution and abundance of different plant and animal communities and species within the area covered by a land and resource management plan (36 CFR 219.3).

ecoregion - A continuous geographic area with similar climate that permits the development of similar ecosystems on sites with similar properties.

ecosystem - A community of organisms and their physical environment interacting as an ecological unit.[3]

ecosystem integrity - System integrity where the system is defined as the degree to which all components and their interactions are represented and functioning within an ecosystem. Integrity is the quality or state of being complete, a sense of wholeness.

ecosystem management-"...management driven by explicit goals, executed by policies, protocols, and practices, and made adaptable by monitoring and research based on our best understanding of the ecological interactions and processes necessary to sustain ecosystem composition, structure, and function."[8]

endemic species - Plants or animals that occur naturally in a certain region and whose distribution is limited to a particular locality.

exotic - Not native; an organism or species that has been introduced into an area.

hierarchy - A general integrated system comprising two or more levels, the higher controlling to some extent the activities of the lower levels; a series of consecutively subordinate categories forming a system of classification.[3]

hypothesis - An assertion or working explanation that leads to testable predictions; an assumption providing an explanation of observed facts, proposed in order to test its consequences.[3]

landscape - A heterogeneous land area with interacting ecosystems that are repeated in similar form throughout.[4]

monitor - To check systematically or scrutinize for the purpose of collecting specified categories of data.

monitoring - A process of collecting information to evaluate whether or not objectives of a project and its mitigation plan are being realized. In land management monitoring is used to describe continuous or regular measurement of conditions that can be used to validate assumptions, alter decisions, change implementation or maintain current management direction.

montane - Of, growing in, or inhabiting mountain areas.[2]

native - Indigenous; living naturally within a given area.[3]

population viability - Relative measure of the estimated numbers and distribution of reproductive individuals in a species population necessary for that species' continued existence; a minimum number of reproductive individuals in a habitat that will both support them and enable them to interact is necessary for a species' maintenance [adapted from 36 CFR 219.9]

resiliency - The degree to which systems adapt to change.

resolution - Separation or reduction of something into its constituent parts; here, the degree of detail incorporated in the data; finer data resolution provides greater detail.[2]

scale - Defined in this framework as geographic extent; for example, regional, sub-regional, or landscape scale.

scenario planning - Planning that focuses on an outline of a hypothesized or projected chain of events.[2]

seral stage - The developmental stages of a plant community not including the climax community; typically, young-seral forest refers to seedling or sapling growth stages; mid-seral forest refers to pole or medium sawtimber growth stages; and old or old-seral forests refer to mature and old-growth stages.

spatial - Of, relating to, or having the nature of space.[2]

species - The lowest principal category of a biological classification distinct from other groups.[3]

stakeholders - Tribal, State, county, local governments, and private land holders, as well as individuals and groups representing local and national interests in Federal land management. This is meant to be inclusive of all organizations and individuals with an interest in Federal lands. This also includes all United States citizens who use, value, and depend upon the goods, services, and amenities produced by federally administered public lands.

succession - Currently: The more or less predictable changes in species composition in an ecosystem over time, often in a predictable order, following a natural or human disturbance. An example is the development of a series of plant communities (called seral stages) following a major disturbance.[5]

systems modeling - Using a model of a system to study (or experiment) with the system itself.[7]

temporal - Related to, concerned with, or limited by time.[2]

viable - Having the capacity to live, grow, germinate, or develop.

virtual system - A system that is the essence of reality but not actual fact, or form.

watershed - The region draining into a river, river system, or body of water.[2]

weed - Any plant growing where it is not wanted.[3]

APPENDIX 1-A

Detailed chronology of events leading to the establishment of the Interior Columbia Basin Ecosystem Management Project.

Date	Northwest Forest Plan	Fisheries	Forest Health	Range
Summer 1988				USDA Forest Service published a proposed rule that responded to findings of a 1987 review. The review identified parts of the existing livestock grazing regulations that required revision and clarification.
Fall 1988	Record of Decision signed for Supplemental EIS for amendment to the Pacific Northwest Regional Guide. Adopted guidelines to manage northern spotted owl habitat on national forests.		USDA Forest Service prepared "Forest Health through Silviculture and Integrated Pest Management: A Strategic Plan". Included initiation of forest health monitoring program.	
Fall 1989	Interagency Scientific Committee was established to address the status of the northern spotted owl.			
Spring 1990	Interagency Scientific Committee report, "A Conservation Strategy for the Northern Spotted Owl" was released. The report addressed Federal lands through a system of habitat conservation areas. US Fish and Wildlife Service listed the northern spotted owl as threatened.			
Winter 1991		Columbia River Basin Anadromous Fish Habitat Management Policy and Guidelines was signed. Recognized the USDA Forest Service's role, support, development, and implementation of an approach to manage of wild and naturally reproducing stocks of anadromous fish. Chief of the Forest Service issued "Riparian Management Strategy." The strategy provided an approach for implementation, goals for accomplishments, a priority action program, and broad-based support. Regional Foresters pledged their commitment to specific habitat measures identified at Hatfield Salmon Summit which included riparian and watershed restoration.		

Winter (January-March); Spring (April-June); Summer (July-September); Fall (October-December)

Date	Northwest Forest Plan	Fisheries	Forest Health	Range
Spring 1991			Malheur, Umatilla, and Wallowa-Whitman National Forests issued "Blue Mountains Forest Health Report Strategies and Recommendations- New Perspectives in Forest Health". They reported on the deteriorating health of the forests in northeast Oregon.	
Fall 1991	Scientific Panel (also known as Gang of Four) on Late-successional Forest Ecosystems delivered a report to Congress that outlined alternatives and scenarios for management.			
Winter 1992	Record of Decision signed for Final EIS on Management for the Northern Spotted Owl in National Forests. Adopted USDA Forest Service alternative which was equivalent of the Interagency Scientific Committee Conservation Strategy.			National Public Lands Advisory Council released a report prepared by ecologists and rangeland managers "Rangeland-Program Initiatives and Strategies". Concluded that the USDI Bureau of Land Management's main objective should be to protect soil, water, and vegetation.
Spring 1992		NMFS listed the Snake River spring/summer/fall chinook salmon as threatened.	Scientific societies formed the Eastside Forests Scientific Society Panel to "initiate a review and report on the eastside forests of Oregon and Washington".	
Summer 1992	Forest Service Chief Robertson announced ecosystem management as the framework for managing national forests and grasslands.			
Summer 1992			Report prepared by the Malheur, Umatilla, and Wallowa-Whitman National Forests on "Restoring Ecosystems in the Blue Mountains". The report provided direction to the Forest Supervisors to continue the use of the ecosystem approach to identify areas in need of restoration work and activities.	
Fall 1992	US Fish and Wildlife Service listed the marbled murrelet as threatened.			Conservation organizations wanted the USDI Bureau of Land Management to improve its grazing administration. USDI Bureau of Land Management organized an Incentive Based Grazing Fee Task Force to consider ways of establishing an equitable fee for federal forage and examining the feasibility of using fee credits to encourage public land stewardship.

Winter (January-March); Spring (April-June); Summer (July-September); Fall (October-December)

Date	Northwest Forest Plan	Fisheries	Forest Health	Range
Winter 1993	Scientific Analysis Team issued their report "Viability Assessments and Management Considerations for Species Associated with Late-successional and Old-growth Forests of the Pacific Northwest.	NMFS listed the Snake River sockeye salmon as endangered.	The "Blue Mountains Ecosystem Restoration Strategy" was submitted to the Regional Forester. The report provided a broad scope of project opportunities. The "Northeastern Washington National Forest Health Proposal" was submitted to the Regional Forester. The report provided a list of projects which would aggressively address the serious problem of declining health. Petition filed by the Natural Resources Defense Council to halt the logging of old growth on the national forests of eastern Oregon and Washington. Concern that habitat for certain old growth associated species was not being adequately provided.	
Winter 1993	Interior Secretary Babbitt issued a public statement that established policy regarding ecosystem management.			
Spring 1993	President Clinton's Forest Conference in Portland, Oregon discussed the state of the forests, economy, and people of the Pacific Northwest.			
Spring 1993		Eastside Forest Ecosystem Health Assessment was issued. The report responded to the request for a scientific evaluation of the effects of USDA Forest Service management practices on the sustainability of eastern Washington and Oregon forested ecosystems.	Eastside Forest Ecosystem Health Assessment was issued. The report responded to the request for a scientific evaluation of the effects of USDA Forest Service management practices on the sustainability of eastern Washington and Oregon forested ecosystems. "A First Approximation of Ecosystem Health, National Forest System Lands, Pacific Northwest Region" was issued. The report provided a generalized snapshot of the overall health/condition of the national forests from an ecosystem framework.	Draft of the Incentive Based Grazing Fee Task Force's study presented. Western Governor's Association drafted resolution on grazing fees. The resolution called for a fee structure that is predictable, affords stability, and is linked to credits for land stewardship.
Summer 1993	President issued a statement on the "President's Forest Plan"; "Management of eastside forests will need to focus on restoring the health of forest ecosystems impacted by poor management practices of the past..." The President directed the USDA Forest Service to develop a scientifically sound and ecosystem-based strategy for management of eastside forests.			

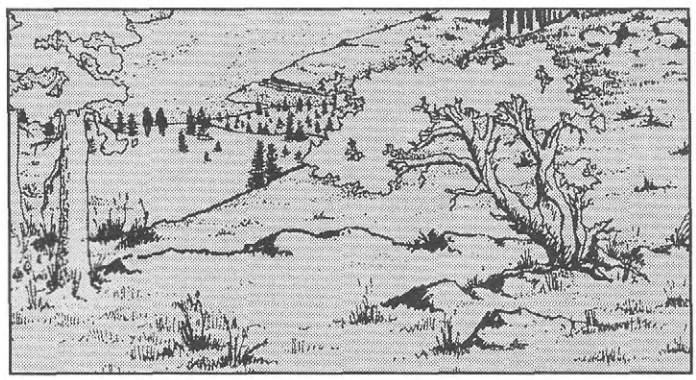
Winter (January-March); Spring (April-June); Summer (July-September); Fall (October-December)

Date	Northwest Forest Plan	Fisheries	Forest Health	Range
Summer 1993	Forest Ecosystem Management Assessment Team issued their report "Forest Ecosystem Management: An Ecological, Economic, and Social Assessment".		Direction provided to screen timber sales where they might affect riparian habitat, reduce the amount of old-growth timber and impact wildlife habitat associated with old growth. Timber industry challenged the "eastside screening" process in court.	Interior Secretary proposes rulemaking intended to revise grazing administration regulations to place greater emphasis on rangeland stewardship and ecological health.
Fall 1993		Umatilla and Wallowa-Whitman National Forests ordered to re-initiate consultation on Management Plans with regard to USDA Forest Service actions to protect listed salmon species. NMFS designated critical salmon habitat.	USDA Forest Service updated their "1988 Strategic Plan" and issued "Healthy Forests for America's Future: A Strategic Plan". The Strategic Plan continued the goals of the 1988 Plan and incorporated new goals that specifically address exotic pests, urban-wildland interface, prevention and restoration. The Idaho Forest, Wildlife and Range Policy Analysis Group published the report "Forest Health Conditions in Idaho".	
Winter 1994		Environmental Assessment for the Implementation of Interim Strategies for Managing Anadromous Fish-producing Watersheds in Eastern Oregon and Washington, Idaho, and Portions of California (PACFISH) is released for public comment.		National Research Council published a report "Rangeland Health: New Methods to Classify, Inventory and Monitor Rangelands".
Winter 1994	USDA Forest Service, USDI Bureau of Land Management, US Fish and Wildlife Service, and NMFS signed an Interagency Memorandum of Understanding to manage federally administered lands for the conservation of species that are tending toward Federal listing. USDA Forest Service was charged with developing a scientifically sound and ecosystem-based strategy for management of forests east of the Cascade crest. The Forest Service and USDI Bureau of Land Management directed that an ecosystem management framework and assessment be developed for lands administerd by the Forest Service and USDI Bureau of Land Management on those lands east of the Cascade crest in Oregon and Washington and within the Interior Columbia River Basin. The Interior Columbia Basin Ecosystem Management Project was established by charter on January 21, 1994.			
Spring 1994	Record of Decision signed for Final Supplemental EIS that amended USDA Forest Service and USDI Bureau of Land Management planning documents within the range of the northern spotted owl, and standards and guidelines for management of habitat for late-successional and old-growth forest related species. (The decision implemented what was known as the President's Forest Plan and later known as the Northwest Forest Plan).		Regional Forester signed a Decision Notice for the "continuation of the Interim Management Direction Establishing riparian, ecosystem, and wildlife standards for timber sales" (also known as Eastside Screens). Amended all eastside (Oregon and Washington) Forest Plans to include the direction as new standards and guidelines.	Draft EIS, "Rangeland Reform 94" was issued.

Winter (January-March); Spring (April-June); Summer (July-September); Fall (October-December)

Date	Northwest Forest Plan	Fisheries	Forest Health	Range
Summer 1994		NMFS issued an emergency action to reclassify the Snake River spring/summer/fall chinook salmon from a threatened status to endangered. US Fish and Wildlife Service announced that the listing of the bull trout was warranted but precluded by higher priority species.	The Eastside Forests Scientific Society Panel reported on their findings and offered interim recommendations for preventing further degradation of remaining resources until more comprehensive data are gathered and long-term protection and restoration can be implemented.	
Fall 1994	Judge Dwyer ruled that the Federal defendants acted within the lawful scope of their discretion in adopting 1994 Forest Plan.	USDI Bureau of Land Management and USDA Forest Service issued a letter of direction for the management of bull trout habitat to ensure that the actions of the agencies do not further contribute to loss of species viability or Federal listing.	The Court enjoined the US Forest Service from applying the August 1993 interim screens to the remaining 1993 sales until it complied with plan amendment and public participation requirements. USDA Forest Service issued their report "Western Forest Health Initiative" to provide a national strategy on forest health. Developed a number of recommendations that build on the "1993 Strategic Plan".	Final EIS was published for "Rangeland Reform 94" (also known as Healthy Rangeland Initiative and Healthy Rangeland Reform). Proposal for managing Federal rangeland administered by the USDI Bureau of Land Management and USDA Forest Service.
Winter 1995		PACFISH Decision Notice/Decision Record was signed by the Chief of the Forest Service and Bureau of Land Management Director to amend regional guides and supplement management direction. Boise, Challis, Clearwater, Payette, Salmon, Sawtooth, and Nez Perce National Forest Management Plans were ordered to re-initiate formal consultation with regard to USDA Forest Service actions to protect listed salmon species. NMFS issued Biological Opinion on eight Forest Service Management Plans that identified goals, objectives, and guidelines that will be applied until the Plans are amended. USDA Forest Service issued an Environmental Assessment for a proposal to protect habitat and populations of native inland fish. This became known as the Inland Native Fish Strategy or INFISH.		USDI Bureau of Land Management published final rule that amended the regulations that govern the administration of livestock grazing. The objectives of the regulations are to promote healthy sustainable rangeland ecosystems, to accelerate restoration and improvement of public rangelands, establish efficient and effective administration, and to provide for the sustainability of the western livestock industry and communities that are dependent.

Winter (January-March); Spring (April-June); Summer (July-September); Fall (October-December)



Date	Northwest Forest Plan	Fisheries	Forest Health	Range
Spring 1995			Decision Notice was signed to revise the decision to implement Interim Management Direction for Eastside Screens. A Report was prepared by scientists in the Northwest for Governor Kitzhaber to help define environmentally sound *timber harvest in eastern* Oregon.	
Summer 1995		Decision Notice for the Inland Native Fish Strategy was signed. The President issues Executive Order 12962 requiring federal agencies to improve the quantity, function, sustainable productivity and distribution of aquatic resources for increased recreational fishing *opportunities.*		
Fall 1995				USDI Bureau of Land Management in Idaho, Utah and Montana issue Notices of Intent to prepare standards for Rangeland Health, guidelines for grazing management, and modifications to land use plans.

Winter (January-March); Spring (April-June); Summer (July-September); Fall (October-December)

EXECUTIVE SUMMARIES

EXECUTIVE SUMMARY- BIOPHYSICAL ENVIRONMENTS

The Biophysical Environments chapter contains multi-scale descriptions of the following systems: geologic, geoclimatic, climatic, potential vegetation, soils, and hydrologic. The biophysical environments described are important to the ecological assessment of the Basin because they:

- Facilitate the delineation and description of terrestrial and aquatic ecosystems that behave in a similar manner given their potential ecosystem composition, structure, and function.
- Delineate areas with similar production potentials for management.
- Provide a basis for interpretations concerning hazards and limitations to management.
- Influence the natural disturbance processes that create finer-scale ecosystem patterns.
- Provide a needed context for the use and development of predictive models concerning future ecosystem pattern and process relations.

Ecosystem characterization is the process of appropriately relating pattern and processes at all scales of interest. It also entails the description and mapping of these patterns and processes. To accomplish this, ecological hierarchies of biotic processes, disturbance processes, and environmental constraints are superimposed. Biophysical environment descriptions and maps identify ecosystems that behave in a similar manner. They provide a useful template for interpretation of features that commonly display change following management or disturbance suppression (for example, existing vegetation). These maps and descriptions are based on landscape components that do not display high temporal variability (for example regional climate, geology, landforms). They often form the basis for delineation of environmental constraints for ecological pattern analysis. Regional, subregional, and landscape scales of biophysical environment maps were developed for use in this assessment. These maps and generalized descriptions of ecosystem components and processes such as geology, soils, climate, and hydrology are included in the Biophysical Environments Chapter.

Summary Characterization by Ecological Reporting Unit

An overview of the major biophysical patterns and hydrologic processes for each ERU within the Basin is presented to highlight differences among them.

Each of the ERU summaries contain:

- Statistics regarding characteristic subsection, lithology, and potential vegetation type composition, and basic climatic and morphometric descriptions.
- Descriptions of generalized soil characteristics and evaluation of productivity.
- Interpretations regarding stream type groups, valley bottom settings, and wetland complexes.
- Interpretations regarding upland erosion processes and sediment sources.

- Interpretations regarding predicted vulnerability of stream channels to disturbances, inherent channel recovery potential, and sensitivity to subwatershed disturbance within each ERU.

Listed below are brief descriptions of the ERU summaries.

ERU 1: Northern Cascades

Two subsection groups dominate:

- M242-01, characterized by glaciated mountains and foothills of igneous and sedimentary rocks modified by glacial and fluvial processes.
- M242-05, characterized by mountains and foothills covered by ash and pumice, frequently underlain by igneous extrusive rocks, and modified by fluvial, mass wasting, and aeolian processes.

This ERU has one of the lowest average elevations (1,216 m), one of the highest relative reliefs, and is in the highest slope class (27%). The area lies in the rain shadow of oncoming Pacific storms.

During the winter enough moisture spills over the Cascade crest to result in substantial snowfall. Overall, annual precipitation is in the highest class (95 cm) unevenly distributed between seasons. The major potential vegetation types are cool, moist; cold, moist; and warm, dry forestlands.

The dominant valley bottom settings are those with steeply sloping and highly to moderately confined valley bottoms and those having gentle slopes with low confinement. Stream types that are characterized by cascades and step-pool systems dominate; however, rapids-dominated B-stream types are very common (see fig. 1.2). Other locally important stream types that are important sources of sediment are braided-systems D types.

The erosion value is in the 65th percentile, the estimated median mass wasting index is at the 81st percentile, and the median sediment delivery hazard is about 78 percent, the highest across all ERUs. Stream channel sensitivity to increased flow and sediment is the lowest of all ERUs. The downstream transfer effects of increases in flow and

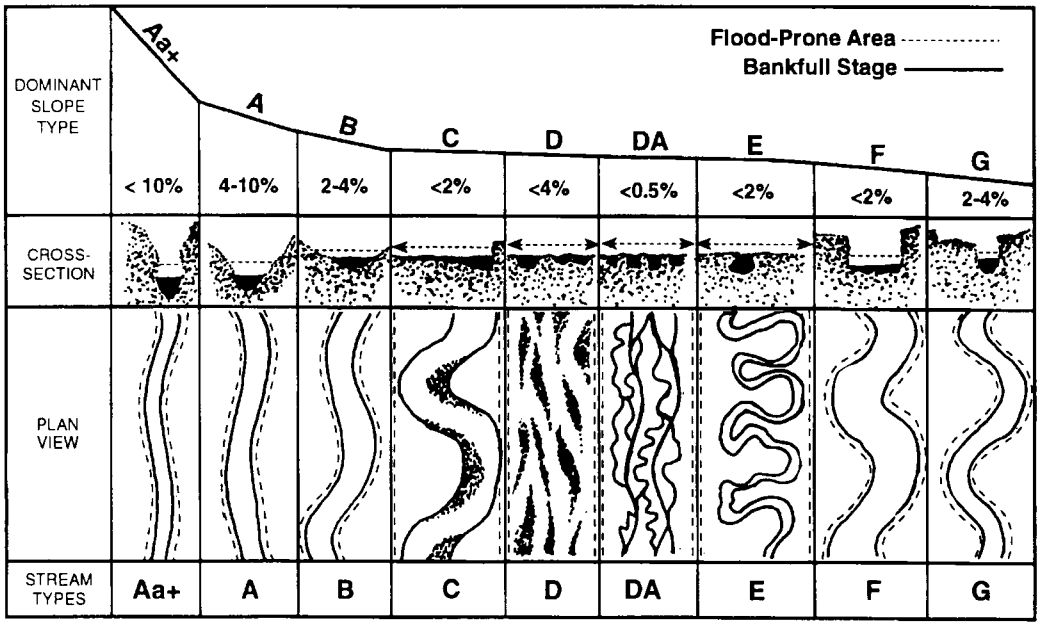

Figure 1.2—Longitudinal, cross-sectional, and plan views of major stream types.

sediment are average. Vegetation is relatively unimportant for maintaining the morphology of the A, B, and D stream types present. Overall, the potential for the estimated dominant stream types to recover from disturbance is among the highest of all ERUs.

ERU 2: Southern Cascades

Three subsection groups dominate:

- M242-05, characterized by mountains and foothills covered by ash and pumice, frequently underlain by igneous extrusive rocks, and modified by fluvial, mass wasting, and aeolian processes.
- M242-01, characterized by glaciated mountains and foothills of igneous and sedimentary rocks modified by glacial and fluvial processes.
- 342-07, characterized by foothills composed mainly of loess over basalt modified by fluvial and aeolian processes.

The lithologic mosaic for this ERU is dominated by mafic volcanic flows and calcic-alkaline volcanoclastics.

This ERU lies in the rain shadow of oncoming Pacific storms. During the winter enough moisture spills over the Cascade crest to result in substantial snowfall. Overall, ERU 2 has one of the highest annual precipitations (100 cm), unevenly distributed between seasons, and is in the highest class for maximum winter temperature. The major potential vegetation types present are warm, dry; cool moist; and cool, very dry forestlands.

The dominant valley bottom settings have steep slopes with low to moderate confinement; moderate slopes with moderate confinement; and gentle slopes with low confinement. Steep A stream types characterized by cascades and step-pool systems predominate, followed by rapids-dominated B stream types and significant numbers of E stream-type reaches with narrow, meandering channels and cool, swift water. Wetlands and lakes account for almost half of the valley bottoms described in subsampling.

The value for erosion is about 45 percent, the value for mass wasting is about 81 percent, and the sediment delivery hazard is in the mid-range (about 38%) of all ERUs.

The median index value for stream channel sensitivity to increases in flow and sediment is low (about 20%), downstream transfer effect of increases in flow and sediment is low, and the median value for potential bank erosion is moderate (about 38%). The importance of vegetation to maintaining the morphology of the dominant channel types is average (about 48%), and the median recovery potential is high (about 80%).

ERU 3: Upper Klamath

Three subsection groups dominate:

- M261-02, characterized by intermontane basins, foothills, and plateaus of igneous extrusive rocks overlain by ash, pumice, and alluvium modified by fluvial and volcanic processes.
- M242-02, characterized by plains of ash and pumice over volcanic rocks, mostly basalt, modified by alluvial and volcanic processes.
- M261-04, characterized by mountains composed of extrusive igneous rocks modified by fluvial processes.

Lake sediments, playas, and alluvium are important lithologic components in some areas.

This ERU has a high average elevation (1,560 m) and some of the lowest relative relief and average slopes (10%). This ERU also lies in the rain shadow of oncoming Pacific storms, but is less influenced by winter moisture that spills over the Cascade crest and results in snowfall. This combination results in the 5th lowest annual precipitation value (57 cm), and is in the highest class of winter solar radiation. The major potential vegetation types of this ERU are warm, dry; hot, moist; and hot, very dry forestlands. Cool, very dry forestlands are also common.

The dominant valley bottom settings are those having gentle valley slopes and moderate to unconfined side-slopes. Steep, confined valley bottoms and moderately steep, moderately confined valleys are also common. Steep, step-pool, A stream types are common, the majority of which are estimated to have unstable channels. Rapids-dominated B stream types are also common, and there is a comparatively high percentage of narrow, highly sinuous E stream types. There is a high percentage of channelized reaches; entrenched, low-gradient F stream types; and a moderate percentage of entrenched, gully G stream types.

This ERU is within the lowest class for upland erosion and has the lowest ranked sediment delivery hazard. It is in the second lowest class for mass wasting hazard and for downstream transfer effects of increased flow and sediment. This ERU ranks second highest in stream channel sensitivity to increases in flow and sediment, with only about 30 percent of the ERUs ranked higher for bank erosion potential. Riparian vegetation is fairly important to maintaining existing channel morphology. This ERU is ranked at the 40th percentile for inherent channel recovery potential.

ERU 4: Northern Great Basin

Three subsection groups dominate this ERU:

- M342-05, characterized by plateaus and foothills composed mainly of tuffs and basalts modified by fluvial and aeolian processes.
- M342-04, characterized by intermontane basins and valleys composed mainly of alluvium, ash, and lacustrine materials over basalt.
- M342-06, characterized by mountains composed mainly of tuffs and basalts modified by fluvial processes.

Lake sediments, playas, and alluvium are present in many subwatersheds.

This ERU occurs at higher elevations (average is 1,566 m), is within the lowest class of relative relief, and has the lowest average slopes. This ERU is in the driest part of the Basin with occasional marine intrusions both winter and summer; it is in the lowest class of annual precipitation, and is in the second highest class of winter solar radiation. The major potential vegetation type is warm, dry shrublands.

ERU 5: Columbia Plateau

Five subsection groups dominate:

- M342-07, characterized by foothills composed mainly of loess over basalt modified by fluvial and aeolian processes.
- M342-03, characterized by plateaus and high plains of fluvial and lacustrine sediments and ash deposits created by aeolian, fluvial, and lacustrine processes.
- M331-02, characterized by intermontane basins and valleys of valley fill, alluvium, and lacustrine materials overlying volcanic and sedimentary rocks.
- M331-04, characterized by glaciated mountains of volcanic and sedimentary rocks modified by colluvial, fluvial, residual, and glacial processes.
- M342-05, characterized by plateaus and foothills composed mainly of tuffs and basalts modified by fluvial and aeolian processes.

Mafic volcanic flows occur on 88 percent of the subwatersheds, and loess deposits occur on 48 percent of all subwatersheds.

This ERU has the lowest average elevation (486 m). It is within the lowest classes of relative relief and average slope (median slope value is about 8%). This ERU is in the driest part of the Basin with occasional marine intrusions both winter and summer; the annual precipitation is about 40 centimeters. This ERU is tied with ERU 2 for the highest average value for maximum winter temperature (about 4.5 degrees C) and is within the highest class of average August temperature (18 degrees C). The dominant potential vegetation types are warm, dry shrublands; warm, dry herbaceous lands; and cool, moist shrubland.

The dominant valley bottom settings are highly confined with steep valley slopes, moderately confined with moderate valley slopes, and moderately confined with gentle slopes. A stream types, characterized by step-pools, are dominant. About two-thirds of these are estimated to be unstable and thus are high sources of sediment. Also common are B and C stream types.

The erosion index is at the 70th percentile of all ERUs, the mass wasting hazard index is the third lowest, and the sediment delivery hazard is about average. The median index values for channel sensitivity to increases in flow and sediment and for bank erosion and downstream transfer effects are the second highest across all ERUs. The importance of vegetation for maintaining the width/depth ratio of the dominant channels is at the 58th percentile across all ERUs, and the recovery potential of streams is low.

ERU 6: Blue Mountains

Three subsection groups dominate:

- M332-08, characterized by mountains composed of igneous, sedimentary, and metamorphic rock modified primarily by fluvial and colluvial processes and secondarily by glaciation, frost churning, and mass wasting.
- M332-07, characterized by mountains composed of igneous and metamorphic rocks with lesser amounts of sedimentary rocks; all of which have been modified by fluvial, colluvial, mass wasting, frost churning, and glacial processes.
- M332-02, characterized by foothills of granitics and volcanics, with some metamorphic and sedimentary inclusions; all of these have been modified by glacial, fluvial, and residual processes.

This ERU falls within the mid-range class for most climatic and elevational data, except that it is within the lowest annual precipitation class. It is in the second highest classes for both winter solar radiation and average maximum winter temperature. A northward migration of a thermal trough during spring and early summer can increase precipitation and cause thunderstorms. The major potential vegetation types are warm, dry forestlands.

The dominant valley settings are highly confined with steep valley slopes, moderately confined on moderate valley slopes, and moderately confined on gentle valley slopes. The high-gradient A stream types and mid-gradient B types occur on over 74 percent of all subwatersheds while low-gradient C, D, and E stream types have moderate distribution. There is a high proportion of unstable, entrenched F types.

The value for erosion (65th percentile) is in the highest category. The median mass wasting index is about the 60th percentile, and the potential hazard for sediment to be delivered to streams is at the 50th percentile. Overall, the recovery potential of steams is low (20th percentile).

ERU 7: N. Glaciated Mountains

Three subsection groups dominate:

- M333-03, characterized by glaciated mountains of granitic and metasedimentary rocks modified by glacial and fluvial processes.
- M333-02, characterized by intermontane basins, valleys and till plains of lacustrine, outwash, alluvium and till.
- M333-04, characterized by mountains and breaklands of granitic and metasedimentary rocks that have been modified by fluvial and colluvial processes with some frost churning and alpine glaciation at high elevations.

Alluvium occurs in 73 percent of all subwatersheds, and open water occurs in 37 percent.

This ERU is in the second highest classes for relative relief: average slope 21%. Westerly flows can result in substantial precipitation, especially at higher elevations, with annual precipitation of about 87 centimeters. It is also in the highest class for summer precipitation (15 cm), and has among

the lowest maximum winter temperatures. The major potential vegetation types of this ERU are warm, dry; cool, moist; and cool, dry forestlands.

The dominant valley bottom settings are steep, confined valleys; broad, gently sloping valleys; and steeply sloping, moderate to unconfined valley bottoms.

The dominant stream types are steep, step-pool A stream types; rapids-dominated B stream types; and meandering, alluvial C stream types with well developed floodplains. Narrow, highly sinuous E stream types also occur. Wetlands and lakes are present in the majority of subsampled watersheds. The erosion potential is among the highest across all ERUs (about the 70th percentile). Median mass wasting hazard and potential delivery of sediment to streams is also high. The overall recovery potential following disturbance is generally good.

ERU 8: Lower Clark Fork

One subsection group dominates:

- M333-04, characterized by mountains and breaklands of granitic and metasedimentary rocks that have been modified by fluvial and colluvial processes with some frost churning and alpine glaciation at higher elevations.

This ERU is among those with the highest relative relief and has the highest average slope (26%). Westerly flows can result in substantial precipitation, especially at higher elevations. It has the highest annual precipitation (111 cm) and the lowest value for winter solar radiation. The major potential vegetation types present are cool, dry; cool, moist; and warm, dry forestlands.

Steep, confined valley bottoms occur in all subsampled watersheds, as do moderately confined and moderate-gradient valley bottoms and broad, unconfined valleys. Steep A stream types dominate. Alluvial, meandering C stream types also occur in all subsampled watersheds. Upland erosion potential is estimated as moderate relative to all other ERUs. Mass wasting potential is highest of all ERUs. The potential for sediment to reach streams is also very high, with most watersheds around the 90th percentile. Watersheds are fairly sensitive to increased streamflow and sediment, both on site and downstream, owing to transfer effects. Riparian vegetation is relatively insignificant in maintaining the channel morphology. Watersheds show the highest sensitivity to disturbance of all ERUs.

ERU 9: Upper Clark Fork

Four subsection groups dominate:

- M332-05, characterized by glaciated mountains and gneiss with lesser amounts of volcanic and sedimentary rocks modified by glacial, periglacial, fluvial, colluvial and mass wasting processes.
- M332-07, characterized by mountains of igneous and metamorphic rocks with lesser amounts of sedimentary rocks; all have been modified by fluvial and colluvial mass wasting processes.
- M332-08, characterized by mountains of igneous, sedimentary and metamorphic rocks modified by fluvial and colluvial processes with lesser amounts of glaciation, frost churning, and mass wasting.
- M332-04, characterized by intermontane basins and valleys of alluvium, lacustrine, and loess deposits modified by fluvial, mass wasting, glacial, and aeolian processes.

This ERU has the third highest average maximum elevation (2,432 m); the fourth highest average slope, and moderate relief. It is in the highest class for summer precipitation (15 cm) and in the lowest class for maximum winter temperatures (-0.3 degrees C). The major potential vegetation types are warm, dry; cool, dry; cold, wet; and cold, moist forestlands.

Steep, confined valley bottoms followed by moderate gradient, moderately confined valley bottoms, and steep, moderately confined valley bottoms occur in subwatersheds. Steep, step-pool A stream types

predominate; rapids-dominated B stream types, meandering-alluvial C stream types, and highly sinuous E stream types are decreasingly abundant. Wetlands and lakes occur in 61 percent and over 60 percent of the watersheds, respectively.

The upland erosion potential is average, and the mass wasting hazard and the potential for sediment to reach streams are ranked at the 60th percentile. Overall bank erosion potential is ranked at about the 30th percentile and the inherent recovery potential of these watersheds is quite high (70th percentile).

ERU 10: Owyhee Uplands

Three subsection groups dominate:

- M342-02, characterized by plateaus and high plains of basalts and tuffs modified by fluvial and aeolian processes.
- M342-06, characterized by mountains composed mainly of tuffs and basalts modified by fluvial and aeolian processes.
- M342-03, characterized by plateaus and high plains of fluvial and lacustrine sediments and ash deposits that have been created by aeolian, fluvial, and lacustrine processes.

Alluvium is present in 68 percent of the subwatersheds.

This ERU has relatively high elevation subwatersheds (1,442 m) and is in the lowest class for relief, average slope (9%). This ERU is in the driest part of the Basin with occasional marine intrusions both winter and summer. It has a low annual precipitation (30 cm) and some of the lowest summer precipitation values (4 cm). It is in the highest August temperature class (18 degrees C), the third highest winter temperature, and is in the highest class for winter solar radiation. The major potential vegetation types are warm, dry; warm, very dry; cool, moist; and cool, dry shrublands.

Gentle slopes in moderately confined valley bottoms and moderate slopes in confined to moderately confined valley bottoms occur in all or nearly all watersheds. Steep, confined valleys occur to a much lesser extent. Steep, step-pool A stream types and rapids-dominated B stream types occur most frequently. Meandering, alluvial C stream types with well-developed floodplains; braided channels; entrenched, gully-like G stream types; and entrenched, meandering F stream types occur as well.

Upland erosion potential ranks at about the 60th percentile. Mass wasting potential and sediment delivery hazard (20th percentile) are low. Potential bank erosion is quite high (70th percentile), with vegetation moderately important in maintaining width-to-depth ratios. Inherent recovery potential following disturbance is among the lowest of all ERUs.

ERU 11: Upper Snake

Two subsection groups dominate:

- M342-02, characterized by plateaus and high plains of basalts and tuffs modified by fluvial and aeolian processes.
- M342-06, characterized by mountains composed mainly of tuffs and basalts modified by fluvial and aeolian processes.

Alluvium occurs in 84 percent of the subwatersheds.

This ERU is characterized by high elevations (1,672 m), low relief, and low average slope (10%). It is in the driest part of the Basin with occasional marine intrusions both winter and summer. It is in the lowest class of annual precipitation (31 cm) and summer precipitation (6 cm), and has high winter solar radiation and high average daily August temperature. The major potential vegetation types present are warm, dry; warm, moist; and cool moist shrublands; and hot, very dry forestlands.

Moderately confined valley bottoms on gentle slopes and confined to moderately confined valley bottoms on moderate slopes are co-dominant. Moderate gradient, rapids-dominated B stream types occur in 93% of subsampled watersheds. Steep, step-pool A stream types occur in almost 80% of the subsampled watersheds. Channelized and entrenched streams occur to a lesser degree.

Upland erosion potential ranks at about the 60th percentile, but mass wasting and potential sediment delivery to streams is low relative to other ERUs. The overall sensitivity of these watersheds to increased flow and sediment is average. This ERU is distinguished by relatively high streambank erosion potential (65th percentile) and low channel recovery potential (40th percentile). Riparian vegetation is especially important for maintaining channel morphology (90th percentile).

ERU 12: Snake Headwaters

Four subsection groups dominate:

- M331-06, characterized by mountains of sedimentary and volcanic rocks modified by colluvial, fluvial, residual, glacial, and periglacial processes.
- M331-02, characterized by intermontane basins and valleys of valley fill, alluvium, and lacustrine materials overlying volcanic and sedimentary rocks.
- M331-03, characterized by glaciated mountains of volcanic and sedimentary rocks modified by colluvial, fluvial, residual, glacial, and periglacial processes.
- M331-04, characterized by glaciated mountains of volcanic and sedimentary rocks; all have been modified by colluvial, fluvial, residual, and glacial processes.

Alluvium is present in 88 percent of the subwatersheds.

This ERU has the highest average elevation (2,191 m), high winter solar radiation, a moderate level of summer precipitation, and low maximum winter temperatures. Relief and average slope (18%) are in the mid-range for all ERUs. The major potential vegetation types are cool moist, and warm dry shrublands; and cool dry, and warm dry, forestlands.

Steep, moderately confined valleys dominate followed by moderately confined valleys on moderate slopes and broad, gently sloping valleys. Steep, step-pool A stream types occur in all subsampled watersheds, as do meandering, alluvial channels with well-developed floodplains. Braided channels also occur over small areas in a majority of watersheds. The mass wasting index is high (80%), but the potential for sediment delivery to streams is only moderate because of low drainage densities. Maintenance of riparian vegetation is fairly important relative to other ERUs.

ERU 13: Central Idaho Mountains

Three subsection groups dominate:

- M332-07, characterized by mountains of igneous and metamorphic rocks with lesser amounts of sedimentary rocks modified by fluvial, colluvial, and mass-wasting processes.
- M332-05, characterized by glaciated mountains and gneiss with lesser amounts of volcanic and sedimentary rocks modified by glacial, periglacial, fluvial, colluvial, and mass-wasting processes.
- M332-01, characterized by breaklands and foothills of granitic rocks modified by fluvial, colluvial, and mass-wasting processes.

This ERU is within the second highest elevation class. It is in the highest relative relief (average slope 26%) and winter solar radiation classes. It is less influenced by precipitation from westerly flows than are the ERUs further north. The major potential vegetation types present are warm, dry; cool, dry; and cold, dry forestlands; and cool, moist shrublands. Steep, confined valleys dominate this ERU.

Moderately confined valleys with moderate slopes and steep slopes are common. Steep, step-pool and cascade streams (Stream type A) occur in all subsampled watersheds. On more moderate slopes, rapids-dominated B stream types, and localized occurrences of braided D stream types are common (93% and 45% constancy respectively). Highly sinuous, narrow, riffle-pool streams (E types) occur in 45% of all subsampled watersheds. Unstable, entrenched F types occur to a lesser extent.

Upland erosion potential is average. Potential for mass wasting and delivery of sediment to streams is quite high (both are at the 65th percentile). Overall sensitivity to increased sediment and streamflow is fairly low (25th percentile), and potential downstream transfer effects caused by increased streamflow and sediment are moderately high (60th percentile).

Hydrologic Integrity

An analysis of hydrologic integrity across the Basin was complicated by a lack of consistent finer-scale data. Stream parameters such as bankfull width, depth, streambed gradient, and substrate composition were generally lacking for most watersheds. As a result, a generalized probabilistic approach was used to estimate subbasin hydrologic integrity. In this approach, information on the resiliency and sensitivity of watersheds to disturbance were combined with estimates of past disturbance to provide an overall hydrologic integrity estimate. Rangeland and forested watersheds were assessed independently in this analysis to facilitate characterization of these environments separately at the subbasin level (maps 1.5 and 1.6). The integrity values reflect probabilities of finding altered hydrologic functions within 4th-field hydrologic units (subbasins) based on relative differences between subbasins.

Values were derived for rangelands and forestlands by subbasin and assigned to high, moderate, and low classes. These integrity values assume that areas with high effect (disturbance) and low recovery potential (resiliency) have higher probabilities of containing altered hydrologic functions than other areas; consequently, they are described as having low integrity. Conversely, areas with low relative effect from mining, dams, roads, cropland conversion, and grazing and that also have high recovery potentials are considered to have the highest probable hydrologic and riparian integrity. More specific descriptions of subbasins with high and low forest and rangeland integrity are shown below. Forest and rangelands with moderate integrity are likely to have some aspects of each of the high and low categories.

Forest lands with high hydrologic integrity have had little disturbance of their hydrologic functions from past activities. In addition, the potential for streams to recover following disturbance is generally moderate to high. Forest lands with low hydrologic integrity have experienced a great deal of disturbance to their hydrologic functions from past activities, which primarily include roads, dams, and cropland conversion of the lower elevation valleys. The potential for streams to recover following disturbance is low to moderate, and sediment hazards associated with roads are moderate to high.

Rangelands with high hydrologic integrity have had relatively little disturbance to their hydrologic functions from past activities; grazing effects on riparian areas are assumed to be generally low. The potential for streams to recover following disturbance is high. Stream sensitivity to increased flow and sediment is relatively low. Stream channel function has a low dependence on the maintenance of riparian vegetation. These subbasins support some of the riparian environments that are most resilient to livestock grazing. Rangelands with low hydrologic integrity have experienced high disturbance of their hydrologic functions from past activities (primarily cropland conversion of valley bottoms and roading). The potential for streams to recover following disturbance is low. Stream channel sensitivity to increased sediment and flow is moderate to high, and streambank sensitivity to disturbance is high.

EXECUTIVE SUMMARY: LANDSCAPE DYNAMICS

Introduction

We address this summary to the stewards of the Basin. We consider stewards to be people that make decisions about landscape dynamics that affect the Basin. This includes public land managers with the Forest Service and Bureau of Land Management and other involved agencies. It also includes other people that influence landscape dynamics on public lands. For example, if you turn on a faucet that runs water that comes from public land watersheds of the Basin, there is an associated effect. If your input to public officials or elected officials influences whether a tree is cut or not cut, a fire is lit or put out, a road is closed or not closed, or a species is recovered or not recovered, you have affected the landscape dynamics of the Basin. From a scientific perspective these associated, and often far-reaching effects, are neither good nor bad. They are the consequences of how society chooses to manage public lands. We hope that the Landscape Dynamics Assessment (Chapter 3) and this summary help the people that influence this "cumulative consensus" to make better decisions about the collective outcome for the land and people of the Basin.

In this summary we move directly to some of our key points and then follow with a synthesis of findings and a summary of results.

Key Points

Landscape ecology has often been misconstrued as vegetation ecology. This is not the case. Landscape ecology is about understanding the interrelationships between human land use, species diversity, ecosystem health, and the inherent disturbance processes and biophysical capabilities of the land (fig. 1.3). The lack of such an emphasis in past analysis has resulted in land management patterns that emphasize individual components rather than the way these components effect one another. *We hypothesized that understanding of these relationships is as important, or more important, than understanding the individual components. Our landscape assessment found this to be true.*

Recovery efforts for species at risk (such as threatened, endangered, candidate, or sensitive species) have been the source of considerable conflict within the past decade, because they have been perceived as placing restrictions on forest or range restoration by limiting management in reserve and buffer areas. In our analysis we *hypothesized that areas with reserve landscape patterns would have higher departure from the historical range of variability (HRV) in disturbance regimes, composition, and mosaic patterns than areas with traditional management. We found this to be false. In fact, we found that areas with the highest levels of traditional management had the highest departure in these characteristics and the highest probability for severe events.*

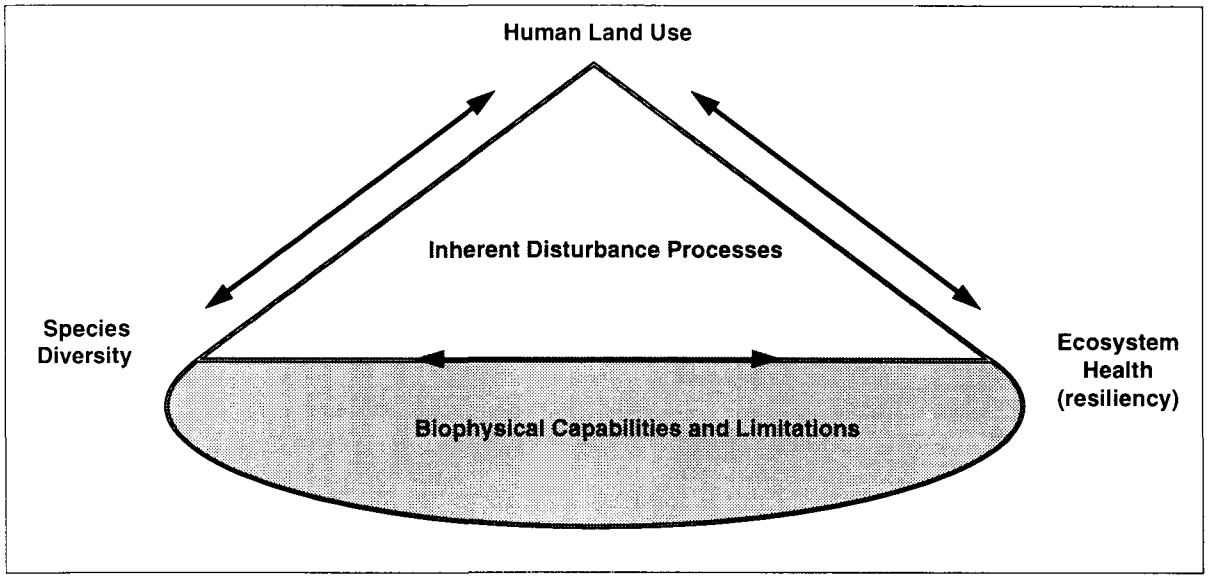

Figure 1.3— Landscape dynamics involves the relationships of human land use, species diversity, and ecosystem health in relation to inherent disturbance processes and biophysical capabilities. Healthy (properly functioning) landscapes provide a "best fit" of the human land uses, species and habitats, and ecosystem conditions that are adapted to the inherent disturbance processes. Outcomes have a high probability for sustained site productivity, a diversity of species consistent with the diversity of habitats, and ecosystem conditions that are adapted to the succession/disturbance regime.

In the assessment we found that most patterns of current forest and range land use activities, habitats for native species, and processes and functions critical to ecosystem health were not consistent with inherent disturbance and biophysical capabilities. We *hypothesized that traditional patterns of land use, whether commodity or reserve, disrupted the inherent disturbance processes and caused a concurrent decline in ecosystem health and native species that depend on such connected relationships. In the assessment this proved to be true* (photos 1.1, 1.2, 1.3, 1.4, and 1.5).

These findings caused us to ask why traditional land management practices caused such high disruption and departure from the native landscape patterns when the traditional objective of each discipline has been to conserve these native characteristics. We *suggest that there is a lack of connectivity between disciplines* (such as forestry, range, fire, watershed, wildlife, fisheries, engineering, recreation) that precludes achieving a landscape perspective. We also *suggest there is a lack of connectivity between management regions* (ownerships and administrative areas) which precludes achieving a landscape perspective.

Native landscape systems, or properly functioning (healthy) landscapes, have relationships between land use, ecosystem health, and species diversity that are in balance with inherent disturbance processes and biophysical capabilities (see fig. 1.3). When relationships between land use, ecosystem health, and species diversity are out of balance with the inherent disturbance processes and biophysical capabilities the landscape system tends towards disequilibrium. We *hypothesized that the disturbance processes of disequilibrium landscapes eventually recalibrate through reduction of productivity and loss of species the biophysical capability and species diversity to a new equilibrium with attendant reductions in land use options. This proved true in both our assessment of management scenarios and our review of the literature.*

Photo 1.1—Commodity landscape patterns have high departure from native patterns because of systematic fragmentation or homogenization of disturbance processes and biophysical mosaics.

Photo 1.2—Wildfire events on commodity landscape patterns in severe fire weather conditions can result in blow-up fire behavior and fire effects.

Photo 1.3—Flood or erosion events are much more severe on commodity pattern landscapes because of cumulative relationships between landscape pattern departure and extensive road networks.

Photo 1.4—Reserve landscape patterns have high departure from native patterns because of homogenization of disturbance processes and biophysical mosaics.

Photo 1.5—Severe fire events and associated erosion in reserve pattern landscapes result in shifting large blocks of late-seral conditions to early-seral and fragmenting biophysical linkages, such as riparian corridors.

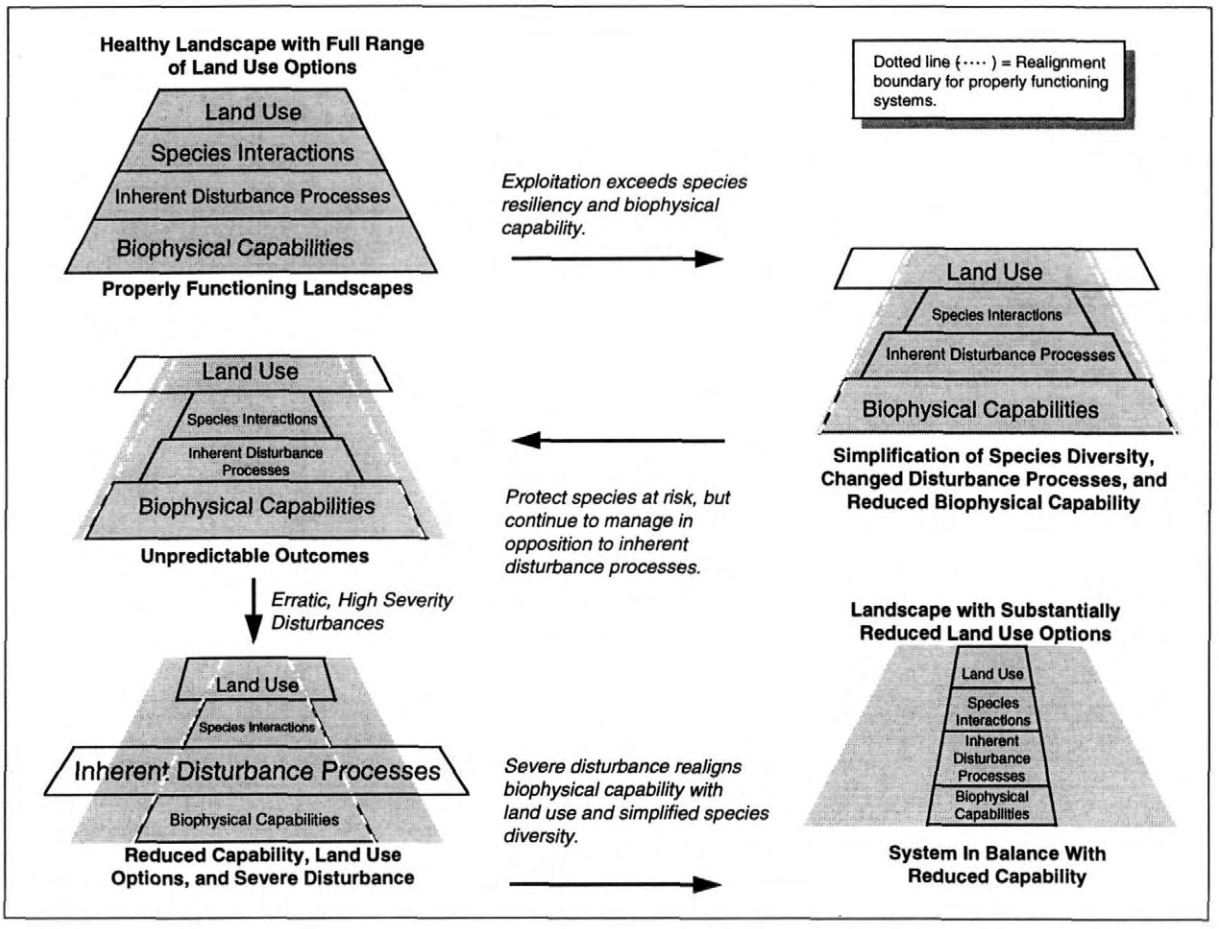

Figure 1.4—Stages in degradation of landscape health in response to land uses that are incompatible with system relationships.

The "stages" in this recalibration can be illustrated as in figure 1.4. In a native or "properly functioning landscape" land use is in concert with the other factors. This stage existed in the Basin during the pre-Euro-American settlement period. Exploitation of species and the biophysical capabilities of land heightened in the Basin during the late 1800s, resulting in simplification of species, changes in the inherent disturbance processes, and a concomitant reduction in biophysical capability. A protection emphasis began in the Basin during the early 1900s with an increasing shift toward protection of individual species by the 1970s. Land use, however, continued to occur in opposition to inherent disturbance processes, disrupting system equilibrium and resulting in continued loss of biophysical capability and system responses that are unpredictable. Many landscapes in the Basin are now entering this stage. This unpredictability can be manifested in high severity disturbances that substantially reduce biophysical capability and land use options. Continued severe disturbances eventually realign biophysical capability with simplified species diversity and a reduced set of land use options. *This process of reduction in biophysical capability and simplification of species diversity, however, can be stabilized at any stage* through change in land use to practices that work

with the land's inherent disturbance processes and are in balance with species adaptations and biophysical capability. Such change would help to restore the system to equilibrium before severe disturbance greatly reduces system potentials.

Our modeling of future scenarios indicates that both traditional reserve (passive management) and commodity (consumptive management) landscape patterns will result in a substantial reduction in biophysical capability, species diversity, and associated land use options. Reduced diversity will be related to exploited elements (such as large trees, native bunchgrasses and predators) or with those species adapted to complex habitat relationships (such as tree cavity nesting/shrubland feeding birds, or species with large migrational patterns). Decline in biophysical capability will occur in the form of reduced productivity (such as from loss of soil, nutrients, or species diversity) and loss of resiliency (in response, for example, to insects, disease, drought stress, competition from exotics, fire or flood). As a result, *landscapes of the Basin will shift to the point where land use will be forced into a new equilibrium, with substantially reduced options, for species diversity and production of human values.*

Our scenario projections of ecological (active management) patterns indicate that current landscapes can be managed with ecological restoration, conservation, and production treatments designed to be consistent with the inherent disturbance processes and biophysical capabilities (photo 1.6). This type of management could shift landscapes at any stage along this continuum back into alignment with the biophysical capability. The native regime and historical range of variability (HRV) provides a sound baseline for understanding ecological restoration, production, and conservation disturbance treatments that can mimic patterns under which the biophysical system and native species have evolved. *However, native patterns or HRV do not provide a sound basis for design of land management objectives or desired conditions.*

Photo 1.6—Native or properly functioning landscape patterns have a balance of land use, ecosystem health, and species diversity that are consistent with inherent disturbance processes and biophysical capability.

Humans are intermingled with wildland mosaics and have different expectations of wildland values than can be produced by mimicking HRV. Landscape response potentials have also been altered by past land use practices which resulted in systems strongly influenced by exotic species, pollution, erosion, and other effects. *However, within the limitations of altered landscapes, ecological restoration, conservation, and production treatments can be designed to provide effective habitats as well as produce other human resource values (photo 1.7). The designs of these treatments are benefitted by concurrent designs of spatially and temporally connected landscapes that support humans, terrestrial and aquatic species, and healthy ecosystems (photo 1.8).*

While we found modeling HRV and analysis of current and future departures from HRV useful at the broad scale, we found that statistical extrapolation of departure of mid-scale landscape mosaic and succession/disturbance regime patterns and fine-scale elements such as snags, fuels, stand density, and species composition

Photo 1.7—Management for native or HRV patterns is not possible in landscapes with altered potentials or complex mosaics of human and wildland conditions. However, management for properly functioning landscapes can be achieved by using an active ecological approach to management of succession/disturbance regimes.

Photo 1.8—Concurrent design of habitats for terrestrial and aquatic species (such as large snags and trees) in connected landscapes (such as for birds that nest in forests and feed in rangelands) restores habitat linkages.

were of equal value in testing hypotheses. From a mid-scale perspective it appears that identification of the range in variability of native (or proper functioning) landscape mosaic patterns across similar geographic areas (regionalization) is the most useful analysis. Such analysis is enhanced when it is coupled with modeling of various options for shifting landscapes to different scenarios of patterns, while protecting critical elements (such as aquatic or terrestrial rare population strongholds, remnant native range, or large trees) and producing or maintaining desired socioeconomic resource values. At the fine-scale, mapping and fitting of landscape management patterns to the biophysical pattern of succession/disturbance regime (hierarchical to the mid scale) that is consistent with the native (or proper functioning) pattern, will likely produce the "best fit" of aquatic/terrestrial habitats and socioeconomic resource values that are consistent with broad-scale objectives.

Synthesis of Findings

Although the conversion of forest and rangeland potential vegetation groups (PVGs) to agriculture (photo 1.9) and other land use is substantial (fig. 1.5) this decline in itself would not be sufficient to cause major disruption in Basin landscape systems. Decline in similarity of physiognomic types, broad-scale and mid-scale fragmentation, increased soil disturbance, and altered forest and range potential vegetation group response is substantial when considered in aggregate. Almost two-thirds of the area across the Basin are restorable to functioning systems, and based on the indices (fig. 1.5) it would appear that landscapes of the Basin are in a moderately healthy condition.

However, the broad-scale data alone do not reflect the gravity of the multi-scale simplification of species diversity, disruption of disturbance processes, decline in ecosystem health, and reduction in land use options (figs. 1.6 and 1.7). The Broad-

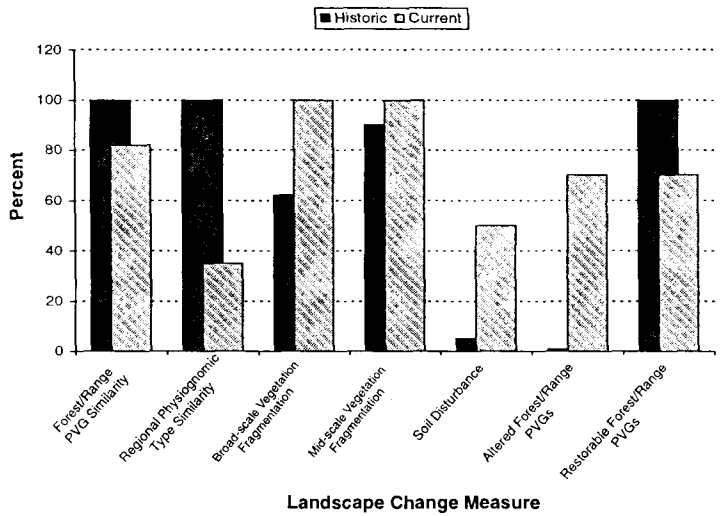
Photo 1.9—Considerable area of forest and rangeland has been converted to agricultural and other forms of land use. These systems can be managed to sustain biophysical capabilities and provide habitats as well as sustained flow of human resource values.

scale Assessment of Aquatic Species and Habitats and the Terrestrial Ecology Assessment (Chapters 4 and 5) indicate substantial declines in native species and habitat quality. We found this to be somewhat correlated with terrestrial community departure, particularly when evaluated spatially using subbasin stratification and other landscape indices. But this broad-scale index of departure does not adequately explain the combined levels of affects on ecological processes and production of human resource values (both commodity and amenity).

We concluded that the broad-scale changes in landscape indices are not adequate indicators of effects on species diversity, forest and rangeland health, disturbance processes (such as wildfire, severity of fire effects, insect/disease mortality, and exotics), and land use resource values that are multi-scale in nature (figs. 1.6 and 1.7). The highest departure in landscape indices is occurring in predictions of mid-scale landscape patterns and succession/disturbance regimes (fig. 1.8). These landscape indices are in almost total departure from patterns that would be in concert with biophysical patterns. Across all ownerships the succession/disturbance regimes and landscape patterns have very low (3%) similarity to the native regime. This includes agricultural and urban lands. Bureau of Land Management- and Forest Service-administered lands have only slightly higher (5%) similarity of these multi-scale indicators. When we compare current land use to native succession/disturbance regimes we find substantially higher departure in the current period. *Combining this low compatibility between land use and succession/disturbance regimes with the generic application of standardized (one-size-fits-all) commodity treatments or reserve protection buffers on variable landscapes has resulted in the current high departure of landscape patterns and succession/disturbance regimes.*

A good example of combined departures is roads on BLM- and FS-administered lands. Road surface area in itself only accounts for 2 percent of the BLM- and FS-administered lands. However, because of the linear pattern across the contour and connected effects on aquatic and terrestrial systems the affected area is approximately 65 percent.

We project that landscape patterns of succession/disturbance regimes could be restored with an active ecological management strategy on a substantial portion of the public lands within the foreseeable future (photos 1.10, 1.11, 1.12, and 1.13). It is *highly probable that this type of strategy could stabilize current declines in terrestrial and aquatic species, ecosystem health, biophysical capability, and land use options, with an associated reduction in erratic and severe disturbance events (fig. 1.9). However, achievement of this future will require change in the kinds and coordination of land use activities, connectivity of disciplines, agency and public collaboration, monitoring, and associated adaptive management.*



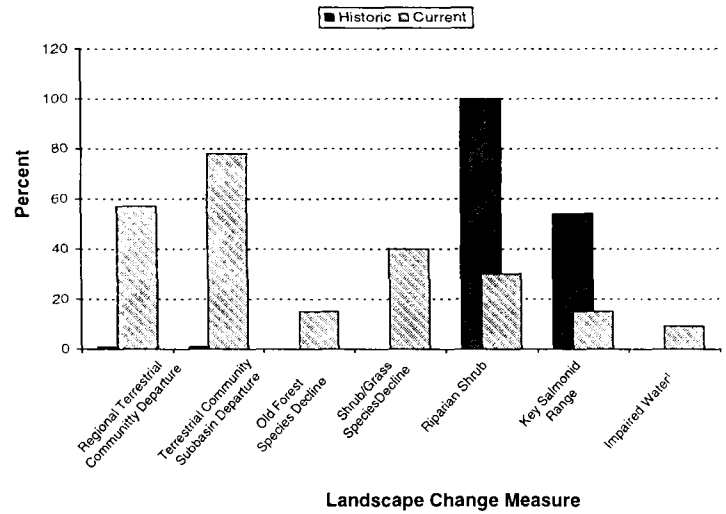


Figure 1.5— Changes from historic or recent historic to current in landscape composition and pattern indices in relation to terrestrial and aquatic conditions.

[1]Impaired water is a legal designation rather than an ecological measure. However, the current amount of impaired water compared to historical water quality is of concern.

Figure 1.6— Changes from historic or recent historic (circa 1960s) to current in landscape composition and pattern indices in relation to landscape health indices and human resource values.

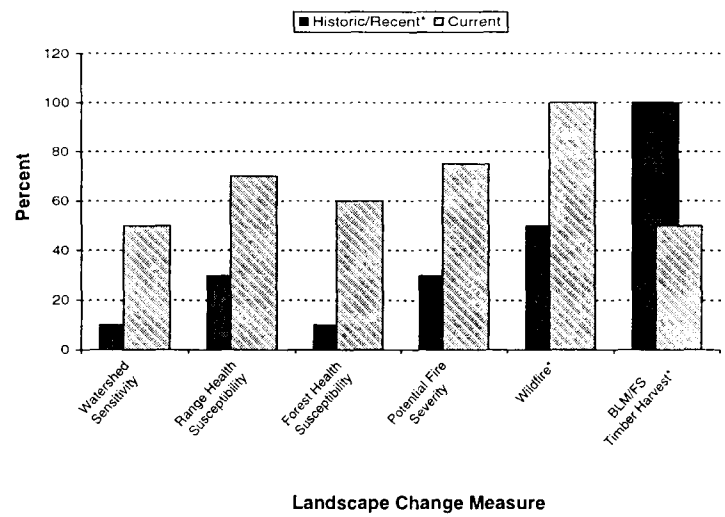

Figure 1.7— Changes from historic or recent historic (circa 1960s) to current in landscape succession/disturbance regime, patterns, correlate with roads, and potentials for ecological restoration. (Note: recent=1960's)

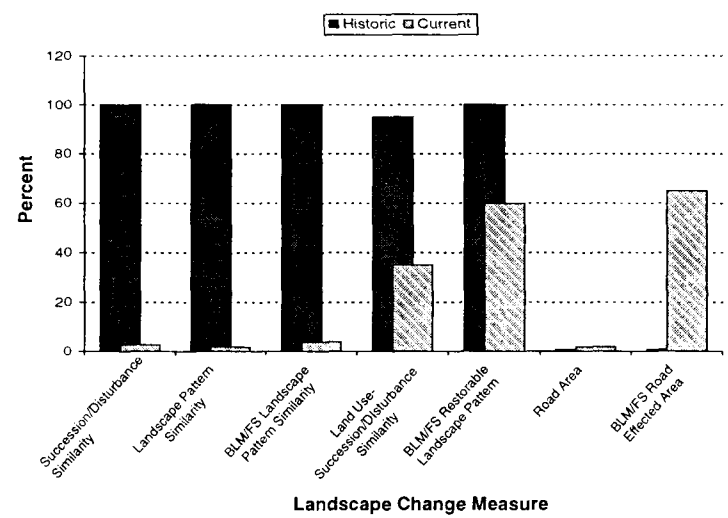

Figure 1.8— Changes from historic or recent historic to current in landscape succession/disturbance regime, patterns, correlate with roads, and potentials for ecological restoration.

Photo 1.10—Invasion of exotic species, such as yellow starthistle, preclude the option of mimicking native patterns. However, active ecological restoration and management to reduce spread can sustain rangelands in patterns that somewhat represent native conditions.

Photo 1.11—Current fuel conditions, concerns about smoke, and urban-rural/wildland interface areas preclude the option for fires of similar size as those that occurred in HRV. However, prescribed fires, thinning, and harvesting planned strategically can be used to produce landscape mosaics and stand structures that represent native systems.

Photo 1.12—Considerable area in forest potential vegetation has shifted to reserve or commodity patterns that do not represent the native pattern. These systems can be managed in the context of properly functioning landscapes and produce desired benefits. A composite regional landscape managed in a properly functioning context could reverse the decline in forest health, forest dependent species, and human resource values.

Photo 1.13—Considerable area in rangeland has shifted to reserve or commodity patterns that do not represent the native pattern. These systems can be managed in the context of properly functioning systems and produce desired benefits. A composite regional landscape could reverse the decline in rangeland health, rangeland dependent species, and human resource values.

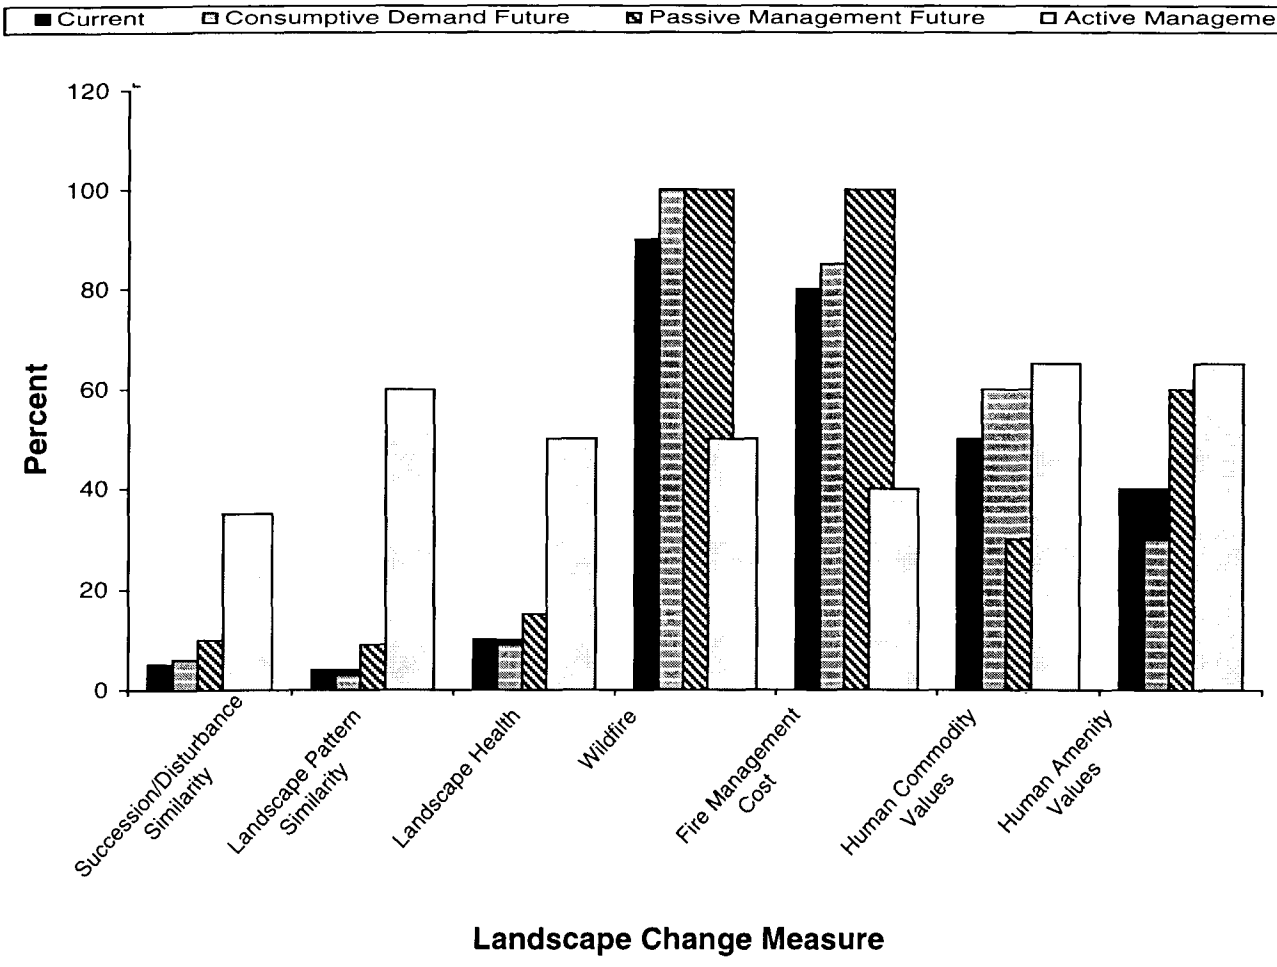

Figure 1.9–Traditional flow of changing outcomes for landscape health.

Summary Overview

We conducted a multi-scale evaluation of the integrity, resiliency, and sustainability of forestland, rangeland, and riparian system functions and processes as part of the overall effort to assess the ecological condition and trends of the Basin. Consequently, our assessment used a regional and landscape perspective to assess biogeochemical, successional, and disturbance processes; vegetation conditions; and landscape patterns across the Basin. We used the concepts of a biophysical template (or biophysical setting) and the historical range of variability as a framework to facilitate understanding of the complex spatial and temporal relationships of these processes and conditions.

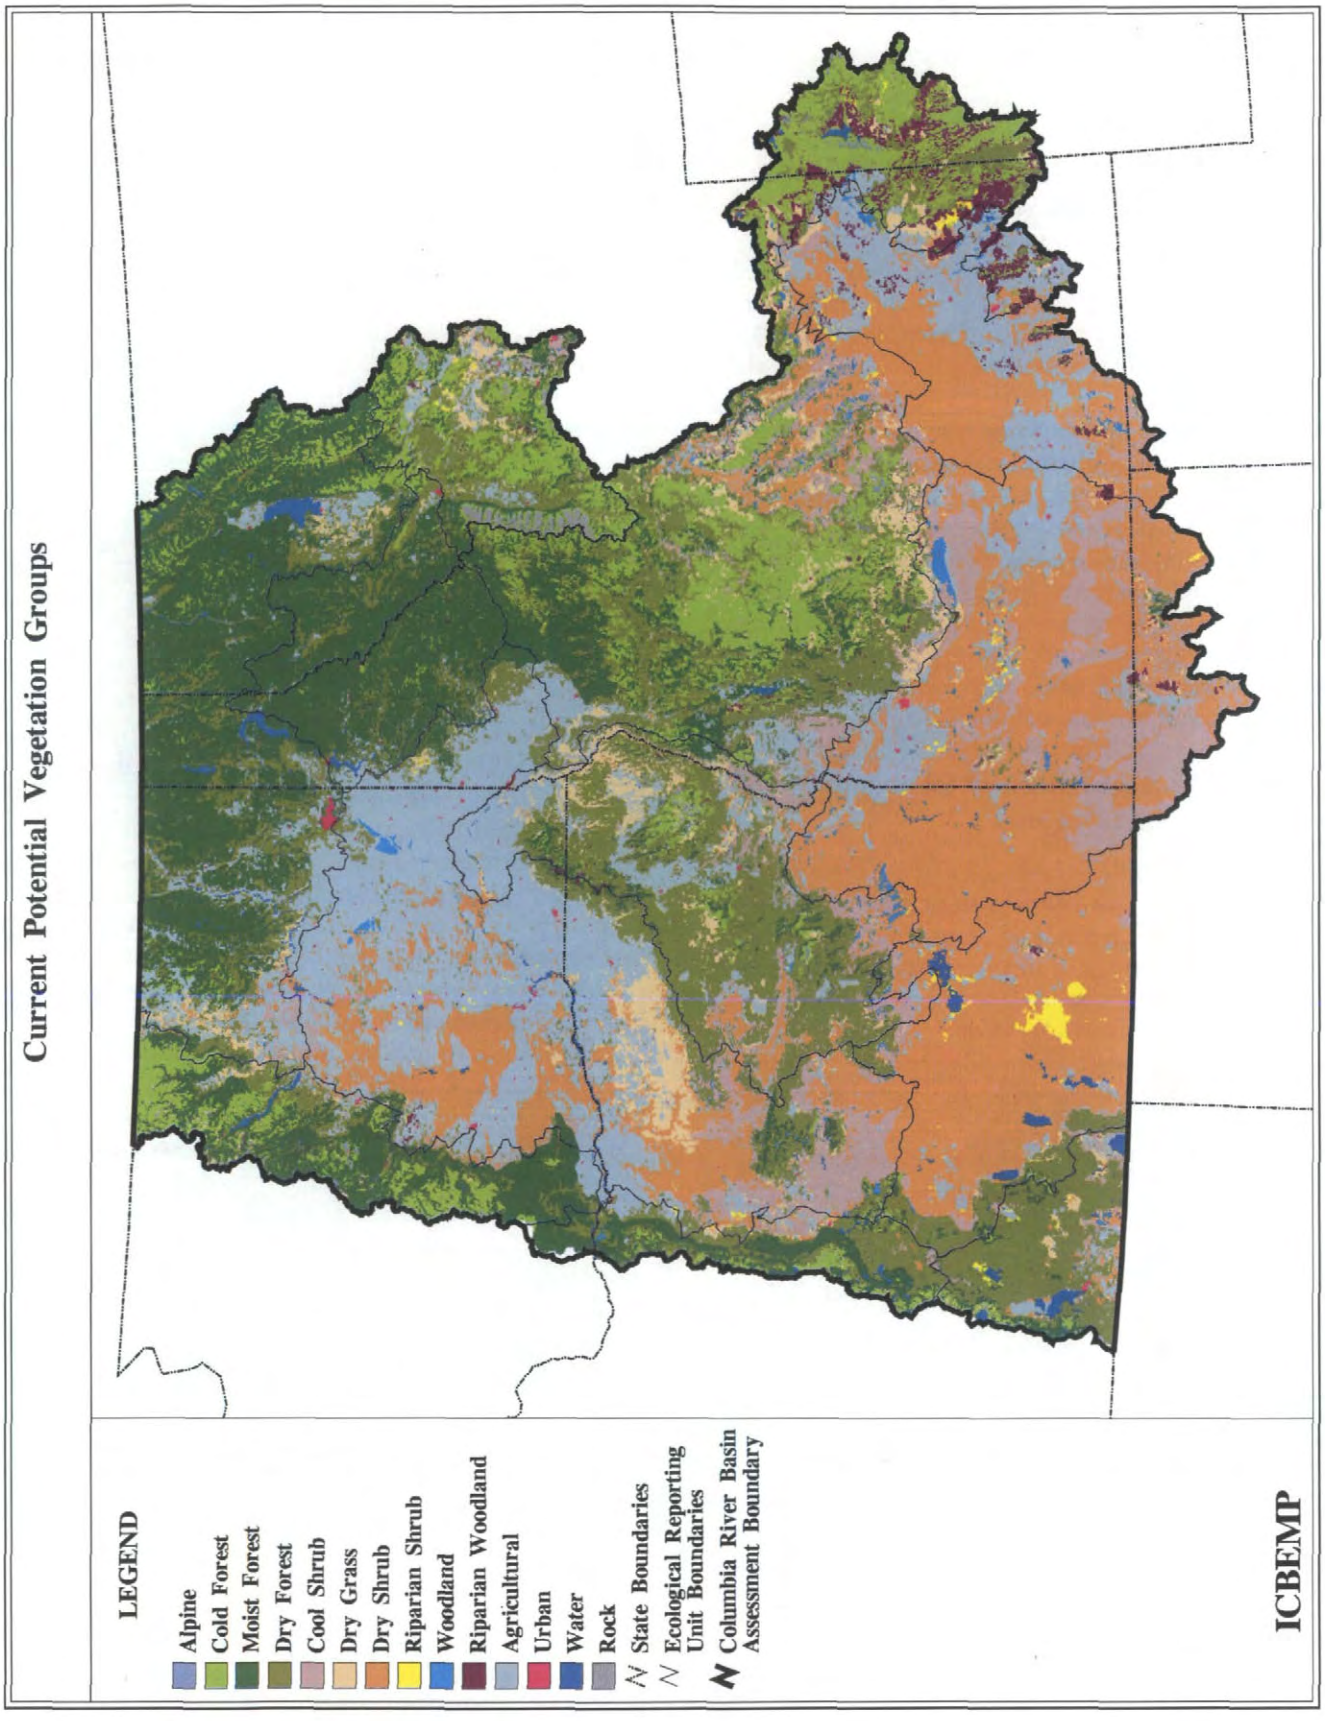
Broad-scale Changes of Biophysical Templates

The biophysical template is the current expression of evolutionary processes, and can be perceived as the biological, physical, and disturbance characteristics of a spatially and temporally explicit environment. We used potential vegetation types, in an aggregate form (potential vegetation groups), as a surrogate of the biophysical environment and site potential.

The Basin contains a complexity of biophysical environments and associated succession and disturbance dynamics. The complexity of biophysical settings is strongly correlated to the interaction of geomorphologic processes and climatic regimes within the Basin. Vegetation patterns, which are subsequently tied to the variety of biophysical settings, also vary widely across the Basin.

As biophysical conditions change as a result of altered topography, soils, or composition of biotic communities, the succession/disturbance regimes are altered as well. Society has expended energy to control or suppress disturbance regimes and successional processes, thereby altering many key

ecological relationships that developed over evolutionary time. Fire suppression; the extensive application of fertilizers, insecticides, and herbicides; the construction of dams; and efforts to produce commodities and values such as timber products, livestock forage, visual conditions, and habitats oriented to specific species (for example, big game cover), are just a few examples of practices humans employ that change the relationships between the biophysical environment and succession/disturbance regimes. In many cases, the alteration of these ecosystem processes has been so extensive that many biophysical settings within the Basin are currently in a state of disequilibrium. Systems in disequilibrium are less resilient to disturbances, and their disturbance responses are less predictable than the responses of systems existing in equilibrium.



Potential vegetation groups (PVGs; that is, aggregations of potential vegetation types) and landforms were used to characterize and stratify broad-scale biophysical environments. We evaluated the trends of PVGs and succession/disturbance regimes to indicate change of biophysical environments. The areal extent and composition of PVGs changed substantially between the historical and current periods (maps 1.7 and 1.8).

Basin-wide, the most intensive alteration of PVGs was attributable to the agricultural development of 17 percent of the Basin between historical and current periods. Less intensive, but more extensive change to the succession/disturbance regimes of biophysical settings occurred as a result of livestock grazing, timber harvest, fire exclusion, flood control, road construction, and the introductions of exotic plants and pathogens. For example, exotic plants have altered the succession/disturbance regimes, productivity, and in some cases, the biophysical setting, of nearly 47 percent of the Basin. Exotic plants are particularly problematic within the rangeland and dry forest PVGs. In forest settings, introduced pathogens have altered the successional pathways and community composition of moist and cold forest PVGs across nearly 22 percent of the Basin.

Within the Basin, the rangeland biophysical environments have changed to the greatest extent. Agricultural development, primarily on the dry shrub, cool shrub, dry grass, and riparian PVGs, is the most intensive change within rangeland systems. Most agricultural practices have substantially altered key ecological processes such as geomorphologic development (that is, soil development and erosion), hydrologic and carbon-nutrient cycles, composition of floral and faunal communities, and ecological food webs. Excessive livestock grazing pressure and the invasion of exotic plants have affected much of the remaining rangelands. Excessive livestock grazing pressure has been implicated in the spread and establishment of exotic annual grasses, which shorten fire-return intervals and dramatically change vegetation composition and structure. Not only has the resilience of these systems declined, but in some cases, the succession/disturbance regimes are still evolving and disturbance responses cannot be easily forecast.

Because of their inherently higher productivity, forest systems seem to be more resilient than rangeland systems. Thus, the biophysical settings within forests have been altered less than those within rangeland systems. In forest systems, fire exclusion, timber harvest practices, and introductions of white pine blister rust within the moist forest PVGs have (1) nearly eliminated western white pine as a dominant species, (2) increased intervals between fires, and (3) increased fire severity. Fire exclusion and blister rust have had a similar effect on biophysical conditions within the cold forest PVG, except that whitebark pine is the dominant species in decline. Although the changes within the cold forest PVG have been less extensive in area, the effect is likely more severe compared to the moist forest PVG. To date, whitebark pine composes the entire forest physiognomy within many cold, high-elevation settings where it dominates the early- as well as late-seral communities. Potentially, this entire forest physiognomy may be replaced by shrubland or herbland physiognomies which could disrupt snow accumulation and hydrologic systems as well as associated terrestrial species.

Map 1.7— Historical (circa 1850-1900) period potential vegetation groups (PVGs). PVGs reflect the vegetation potentials (without disturbance) in relation to climate and other physical characteristics. This map represents average conditions at the time of Euro-American settlement.

Map 1.8— Current period potential vegetation groups (PVGs). PVGs reflect the vegetation potentials (without disturbance) in relations to climate and other physical characteristics. This map represents average current period (circa 1990) potentials.

Road density classes were found to be strongly correlated with the observed changes of extant PVGs because roads were closely associated with modern anthropogenic activities. Road density was found to be indirectly correlated with: (1) the distribution and spread of exotic plants, (2) many forest composition and structural changes, (3) efficacy of fire suppression activities, and (4) the probability of fire occurrence due to human-caused ignitions. In forest systems, roads were associated with timber-management practices and thus correlated with the transition of shade-intolerant to shade-tolerant species, the loss of late-seral structures, reduced densities of large trees and snags, and increased fuel loadings. In rangeland systems, roads appear to function as vectors for dispersing exotic species. Regardless of the biophysical setting, roads appear to increase the efficacy of fire-suppression activities.

Broad-scale Changes of Succession/ Disturbance Regimes

We found little (less than 25%) similarity between the historical and current succession/disturbance regimes within forest and rangeland systems. With few exceptions, disturbance frequency declined as the severity of disturbance increased. Exceptions to this general trend are the dry grass and dry shrub PVGs that have been invaded by exotic annual grasses. In these instances, fire disturbance has become more frequent. Not surprisingly, the departure of succession/disturbance regimes on BLM- and FS-administered lands was less dramatic than the changes that occurred on other ownerships.

Fire Regimes

The resemblance between historical and current fire regimes within forest and rangeland systems ranged from low to moderate depending on the PVG. In forest settings, the current fire regimes of cold forests were most similar to the historical regimes. The current fire regimes of dry forests were least similar. Of the rangeland settings, the current fire regimes of the dry shrub PVG had the least similarity with the historical regimes, primarily because of the effects associated with the invasion of exotic annual grasses and excessive livestock grazing. The current fire regimes of the cool shrub PVG were the most similar to historical regimes within rangeland systems. As with succession/disturbance regimes, the departure of fire regimes that occurred on other land ownerships was more dramatic than that which occurred on BLM- and FS-administered lands.

The changes in vegetation composition and structure of forests and rangelands that occurred between the historical and current periods have substantially increased the risks of wildland wildfires at both the landscape and regional levels. Although wildfire-suppression activities have been successful in reducing the areal extent of wildfires since the early- to mid-1900s, it now appears that the more recent trends may be changing and firefighters may be losing the battle. That is, even though land managers have been allocating increasing amounts of resources to wildfire suppression, suppression efficacy seems to be declining. In fact, the current areal extent of wildfires is approaching that experienced in the early 1900s. Fuel loadings have steadily increased as a result of suppression efforts and the subsequent decline of fire frequencies. As a result, fire severity has increased, as have suppression costs and the associated hazards to life and property. The average costs of wildfire suppression, number of firefighter fatalities, and areal extent of high-intensity fires during the last 25 years have exceeded the corresponding levels that occurred between 1910 and 1970.

Further complicating matters, human populations within the wildland/urban interface have substantially increased within the last few decades. These areas of rapidly-growing human populations are commonly associated with high fire risks.

Broad-scale Changes of Biogeochemical Relationships

The observed transitions of succession/disturbance regimes and vegetation structure and composition were directly associated with changes of biogeochemical processes. Biogeochemical processes are the basic chemical responses of biota to their environment measured in the form of growth, stress, and nutrients. Net primary productivity increased in forests that experienced transitions from shade-intolerant species to shade-tolerant species. In rangeland settings, net primary productivity declined in areas invaded by exotic grasses and forbs, whereas net primary productivity increased in areas converted to agricultural uses. Although carbon stress is inherently associated with moisture availability, it fluctuated with observed transitions of vegetation conditions. In forest settings, carbon stress increased as single-layered stands developed multi-layered canopies, but decreased as the ratio of shade-tolerant to shade-intolerant species increased. Water stress increased in association with successional development, due to increasing amounts of live biomass respiration. Nutrient availability declined with successional development, and as single-layered forests developed multiple layers. Nutrient availability also declined as herblands developed into shrublands, and as herblands or shrublands transitioned to woodlands and forests.

General Landscape Patterns

Landscape patterns at a subbasin level were dependent upon type of landscape mosaic, landform, and the composition of biophysical settings, vegetation conditions, succession/disturbance regimes, and historical land uses. We compared current landscape patterns with those expected in systems dominated by native processes, and to those expected to result from traditional commodity or reserve management strategies. Succession/disturbance regimes resulting from traditional commodity and reserve management strategies would likely change vegetation conditions, and consequently, landscape patterns. Further, intervals between disturbances would increase, but so would the severity of these disturbances. The effects of disturbances could be more acute or more chronic than those associated with native systems.

An examination of current landscape patterns revealed that only 2 percent of the Basin had landscape patterns similar to native patterns, whereas 16 and 64 percent had patterns similar to those expected from traditional reserve and commodity management strategies, respectively. Current landscape patterns of BLM- and FS-administered lands were comparable to the patterns of the Basin as a whole, except that these lands had substantially more area (29%) resembling the patterns expected from a reserve management strategy.

Regional Cover Type Trends

Few cover types occurred within their median 75-percent historical ranges during the current period. In rangeland settings, agricultural development was primarily responsible for areal declines of the fescue bunchgrass, wheatgrass bunchgrass, big sagebrush, and native forb cover types. Areal transitions indicated that the invasion of exotic species occurred predominantly in the big sagebrush cover type, and to a lesser extent, the wheatgrass bunchgrass, mountain big sagebrush, and fescue bunchgrass cover types.

Forest settings were dominated by transitions of shade-intolerant tree species to shade-tolerant tree species. For example, within the dry forest PVG, the areal decline of interior ponderosa pine was mostly attributable to increases in the grand fir/white fir, and interior Douglas-fir cover types. Similarly, the composition of moist forests composed by early-seral, shade-intolerant western larch and western white pine became dominated by Douglas-fir, lodgepole pine, or grand fir/white fir cover types. Lastly, cold forests were affected by the conversion of the whitebark pine cover type into the Engelmann spruce/subalpine fir cover type.

Regional Trends of Terrestrial Communities

The areal extent of most (83%) terrestrial communities occurred outside of their median 75-percent historical range. No terrestrial community within rangeland settings occurred within its historical mid range during the current period. The flux of forest communities was dominated by the transitions of early- and late-seral communities into mid-seral communities. Forest transitions were attributed to the synergistic influences of fire exclusion and timber harvest practices. Timber management practices reduced the areal extent of late-seral communities, and limited the regeneration period of early-seral stands, whereas fire exclusion limited the recruitment of early-seral communities. The departures of community composition from the historical systems seemed to be the greatest in dry forests, and least in cold forests.

Forest and Rangeland Integrity

We characterized the ecological integrity of forests and rangelands at the subbasin level. Because ecological integrity could not be measured directly, relative integrity values were estimated from the departures of broad-scale indicator variables. Both direct and indirect indicator variables were used including PVGs, cover types, changes of fire disturbance regimes, and road densities.

Subbasins having the highest forest integrity values were largely unroaded, and composed of cold forest PVGs, or a mixture of moist and cold forest PVGs. Conversely, subbasins composed of a relatively large proportion of the dry forest PVG that had been intensively roaded, typically had the lowest forest integrity. Forest integrity was thus strongly associated with the efficacy of fire exclusion, the intensity of timber management, and the degree to which succession/disturbance regimes have changed within a subbasin. Most (59%) of the forested subbasins were characterized as having low forest integrity, whereas substantially fewer (23%) were characterized as having high forest integrity.

Most (69%) of the rangeland subbasins were characterized as having low rangeland integrity. In contrast, few (8%) rangeland subbasins had a high rangeland integrity. In general, the subbasins characterized with low rangeland integrity had high compositions of agricultural development or dry grass and dry shrub PVGs, which were indicative of their susceptibility to exotic plant infestations and their lack of recovery potential from excessive livestock grazing.

Modeling Scenarios

We modeled future (100-year) projections resulting from three management scenarios: (1) consumptive demand (that is, traditional commodity production); (2) active ecological management; and (3) passive management (that is, traditional reserve management). Overall, an active management strategy seemed to result in outcomes most beneficial to both humans and native systems. The consumptive demand scenario resulted in outcomes that were typically least similar to the native regime. Ironically, although the passive and consumptive demand scenarios had radically different objectives, their outcomes were surprisingly similar because the passive scenario also has disturbance processes that are inconsistent with biophysical capabilities and species adaptions.

Proper Functioning Landscape Systems

Proper functioning landscapes are "those landscapes whose processes are in a dynamic equilibrium (including the production of human values), such that the rates and routes of key processes and disturbances are resilient and have predictable responses to disturbance. The assessment of proper functioning landscape systems (PFS) is a process which strategically links the "driving variables" of the key ecological processes and predicts responses at hierarchical landscape scales. This provides a process for integration of ecosystem health assessment based on complex relationships between land use, species interactions, inherent disturbance processes, and biophysical capabilities.

EXECUTIVE SUMMARY: BROAD-SCALE ASSESSMENT OF AQUATIC SPECIES AND HABITATS

The Broad-Scale Assessment of Aquatic Species and Habitats addresses the aquatic resources within the Interior Columbia Basin Ecosystem Management Project assessment area. It is directed along four primary themes: a broad characterization of the geophysical and biological settings that define the natural potential of the Basin to provide for aquatic resources; anthropogenic factors that affect aquatic habitats and species, with special emphasis on effects of Federal land management; a broad-scale assessment of the current condition of aquatic habitats and species, primarily fishes; and a synthesis of information in order to provide a regional context for Federal management strategies to protect and restore aquatic and riparian habitats.

Geologic and geomorphic processes formed and continue to affect the Basin. These processes, in concert with the underlying physical environment, establish the template and constrain the successional pathways for aquatic habitats and their associated communities. Similarly, natural fluctuations in the marine environment due to variation in atmospheric and oceanic circulation patterns influence the productivity of anadromous fish stocks. They may temporarily mask changes in freshwater habitats.

Human effects predated Euro-American settlement but increased dramatically with technological development. By the mid-1800s, Euro-American settlers had begun to substantially alter the Basin's landscape and aquatic habitats. Large dam construction began about 1900. The dams have greatly reduced the range of migrating fish. Fish spawning and rearing areas in the upper Columbia River Basin were isolated after the Grand Coulee (1941) and Chief Joseph (1955) dams were completed. Since 1967, Hells Canyon Dam has blocked anadromous fish access to the Snake River and tributaries above the dam. A similar loss of most spawning and rearing habitats followed the construction of Cabinet Gorge Dam on the Clark Fork River above Lake Pend Oreille. Today there are at least 1,239 large dams in the assessment area, each with storage capacity in excess of 62,000 cubic meters. If small dams are included, the total storage capacity could be several times larger. There are thousands of small dams in the Basin, and most do not have fish passage facilities. The full extent to which these dams impede migration or affect spawning and rearing habitats of fishes has not been documented. Even though the rate of increase in storage volume has leveled since the mid-1970s, the total number of dams continues to increase, suggesting that new construction is focused on smaller dams. Even with fish passage facilities, detrimental effects from dams occur. Direct mortality of juveniles continues in turbines and bypass systems. Indirect mortality is caused by physiological stress, increased susceptibility to predators, and the inability to find routes around dams and through slack water.

According to U.S. Environmental Protection Agency estimations, overall water quality impairment within the Basin appears to be modest compared with total length of streams. Because these

estimates are based on existing and accessible data from locally specific State and Federal monitoring programs, they likely do not reflect the real extent and distribution of impairment. Many streams identified by the Forest Service as having elevated temperatures were not identified in Environmental Protection Agency assessment reports. In addition, water withdrawals for offstream uses can reduce instream flows significantly. This can alter or eliminate habitat and affect water quality. Most streams in the region are now fully or over-appropriated. Irrigation is the primary offstream use of water in the Basin.

To look at changes in riparian vegetation we conducted a mid-scale, Basin-wide analysis. The analysis showed significant changes. There was a decline in shrublands in the riparian zones in more than half of the ERUs. Shrublands predominantly shifted to forests and herblands through succession or disturbance. Forests, woodlands, and herblands increased in area or stayed approximately the same. Cottonwood, aspen, and willow, typically riparian-associated species which are known to have significant declines, are included in the forest class. However, they are likely masked by the dominance of other species in this class. These cover types decreased in 6 of the 13 ERUs. Significant decreases occurred in the Snake Headwaters and Columbia Plateau. Significant increases in woodlands occurred in the Northern Great Basin, Blue Mountains, and Columbia Plateau. This increase is attributed to shrubland conversion to juniper stands. The integrity of riparian vegetation and its extent along rivers has been changed and fragmented throughout the Basin in response to forest conversion and streamside disturbance.

Stream Habitat Features

We used stream-inventory data and landscape information to detect and characterize land use effects on aquatic habitats. For decades various agencies have routinely inventoried streams within their jurisdictions in order to monitor key aspects of stream-channel conditions. These inventories provide a rich source of information for comparison across broad geophysical settings and management regimes. They also permit historical comparisons in some areas. Many historically surveyed streams were resurveyed recently throughout the Columbia River Basin. Changes in habitats were analyzed using the information from the resurveyed streams.

Results of survey information and tests of relationships among habitat features, landscape features, and disturbance variables reinforce the evidence that streams within the assessment area have been significantly affected by human activities. Major decreases in pool habitat have been caused by two factors: the loss of riparian vegetation, and road and highway construction accompanying human activities (such as timber harvest, grazing, and farming). Most notably, pool frequency (large pools and all pools) is inversely correlated with road density and management intensity. The losses appear to have been the greatest in the lower-gradient, biologically-productive areas of river basins most disturbed by humans. The magnitude of decreases in deep pools is substantial and extensive regardless of ERU. The unmanaged streams that were resurveyed generally are in steeper and more highly dissected landforms within the Columbia River Basin and therefore would have had fewer large or deep pools. Most unmanaged streams either have retained pools or have improved pool habitat during the last 55-60 years.

A factor likely to be important in controlling pool frequency in the Columbia River basin is the abundance of in-stream wood. There is a correlation between wood frequency and pool frequency throughout the assessment area. This occurs most notably between large-wood and large-pool frequencies on low-gradient streams. Wood effectively stabilizes channels, influences sediment routing, provides a major component of the in-stream organic matter, provides cover for fish and habitat for invertebrates, and increases overall channel complexity. Protecting sources of in-stream wood for streams is important because:

wood is not readily available in many areas; it plays a critical role for pool formation and habitat conditions; and wood frequency is sensitive to management practices.

The amount of fine sediment (sediment less than 6 mm) on channel beds is another important aspect of habitat quality that apparently is influenced by management. The results of our analysis indicate road density significantly affects surface fines and corroborates the link between forest management practices and channel sediment characteristics.

The role that low-frequency events have in controlling channel morphology, is an aspect of channel conditions in the assessment area that has not been explicitly evaluated in this analysis. Events such as large floods, mass movements, and fire can profoundly affect stream channels by introducing and/or mobilizing large quantities of sediment, thereby altering bed structure and channel form in manners that can persist for decades to hundreds of years. Past human activities can strongly influence the timing and magnitude of natural events. Clearcutting and watershed disruption are linked to increased water yields, bedload movement, more frequent flooding and scour events, and channel instability. Long-term risk to fish and fish habitat on a regional scale is affected by potential long-lasting perturbations to channel conditions.

Status and Distribution of Fishes

A total of 142 fish taxa were reported within the Basin. We considered the fishes at three levels listed in order of increasing detail: 1) fish species assemblages, 2) sensitive native species, and 3) key salmonids. We summarized the known occurrence of all native and introduced fish taxa, defined species assemblages, and calculated richness and diversity indices. We compiled information for 38 taxa considered sensitive, threatened, endangered, or of special concern. We then considered seven select salmonids in the greatest detail: bull, westslope cutthroat, Yellowstone cutthroat, and redband trout; steelhead; and ocean-type (age-0 migrant) and stream-type (age-1 migrant) chinook salmon.

Our analysis was based on both a summary of known distributions and the prediction of distributions and status for select species throughout the entire assessment area. Classification of status for key species and distribution for all species, native and introduced, was supported by information collected through more than 140 biologists working throughout the region. We organized our conclusions along four major themes: 1) composition, distribution, and status of fishes; 2) areas with strong populations; 3) system integrity; and 4) intensively managed areas.

Composition, Distribution, and Status of Fishes

The composition, distribution, and status of fishes within the Basin is very different than it was historically. The overall changes are dramatic and extensive, and in many cases irreversible. Some forms are extinct. Many others, especially anadromous fish, are extirpated from large portions of their historical range. Our clearest understanding of fish status comes from the analysis of the seven key salmonids and is supported by our analysis of species assembages. Although several of the key salmonids remain distributed through much of their historical ranges (notably the cutthroat trouts and interior redband trout), declines in abundance, the loss of important life histories, local extinctions, and fragmentation and isolation of high-quality habitats are apparent. Wild chinook salmon and steelhead are approaching extinction in a major part of the remaining distribution.

If current distributions of the key salmonids are good indicators of aquatic ecosystem health, many systems are only remnants of what were larger and more complex, diverse, and connected systems. Even with no further habitat loss the fragmentation and isolation may place remaining populations at risk. With the exception of the Central Idaho Mountains, Snake Headwaters, and perhaps the Northern Cascades, most of the important areas for the key salmonids exist as patches of scattered watersheds. Many are not well connected or are restricted to much smaller areas than historically.

Many of these important watersheds are associated with high-elevation, steep, and more erosive landscapes. These areas may have more extreme or variable environments contributing to higher variability in the associated populations and higher sensitivity to watershed disturbances. Risks could be aggravated by further development.

The patchwork of important watersheds also suggests that remaining populations are not well distributed within the subbasins. Watersheds that were once likely to support a complex of life-history patterns and subpopulations within larger regional or metapopulations are now often fragmented. The loss of spatial diversity in population structure and of the full expression of life-history pattern may lead to a loss of productivity and stability important to long-term persistence.

Although we know less about the rare and sensitive fish taxa than about the seven key salmonids, analyses of existing distribution and reviews of available literature provide important insights about common threats and appropriate management needs. Many of these taxa occur in isolated areas of the Columbia River basin, in isolated subbasins of the Great Basin, or are restricted to the Upper Klamath Basin. They typically occur in relatively depauperate subbasins, perhaps with only one or two native fish species present and in very restricted areas, often occupying one or two small habitat patches within subwatersheds (averaging 8,000 ha in size). Consequently, broad- or mid-scale assessments that focus on high native species diversity may not adequately describe their distributions.

Areas with Strong Populations

Though much of the native ecosystem has been altered, core areas remain for rebuilding and maintaining functional native aquatic systems. Even though they are reduced in numbers and distributions, native trout remain one of the most widely distributed taxa within the Basin. These indicators of environmental quality suggest that although we have serious problems, particularly in the larger rivers and in the low-elevation agricultural and range lands, the situation is somewhat better in the forested lands. Conditions remain the best in those areas that have experienced the least human-caused disturbance. We see a higher proportion of strong populations in higher-elevation forested lands than others, and the proportion declines with road density. Most of the areas exhibiting high aquatic integrity fall within forested areas, with the exception of areas inherently high in native species richness near the southern edge of the Basin.

The largest areas of contiguous watersheds supporting strong populations of key salmonids are associated with the major river subbasins found in the Central Idaho Mountains, the Snake Headwaters, and the Northern Cascades ERUs. Important but more restricted areas are also found in the Blue Mountains, Upper Clark Fork, and the Northern Glaciated Mountains. Each of the key salmonids had some known or predicted strong populations. Strong areas for salmonids occurred in from less than 1 percent of available subwatersheds for stream-type chinook salmon to 34 percent of available subwatersheds for Yellowstone cutthroat trout (table 1.5). There are few clusters of subwatersheds likely to provide highly productive habitat for multiple species, but collections of watersheds still exist within larger subbasins. However, the core for maintaining and restoring much of the biological diversity associated with fishes still exists.

System Integrity

Protection and maintenance of system integrity and functioning will require innovative approaches. Simple solutions such as setting aside small, scattered watersheds probably will not be adequate for the persistence of even current distributions and diversity. The problems are too complex and too pervasive. If maintenance or restoration of aquatic ecosystem integrity is an important goal, dramatic and decisive action is required to stop further alterations and restore areas that are degraded. Aquatic diversity and resilience are dependent on the maintenance of complex habitats and networks of those habitats at multiple scales.

Table 1.5—Current population status of seven key salmonids in the Basin and its relationship to lands administered by the Forest Service (FS) and Bureau of Land Management (BLM). Data are based on counts of subwatersheds.

Species	Percent of Historical Range Occupied	Percent of Occupied Range Classed as Strong	Percent of Strongholds in Wilderness	Percent of Strongholds on FS/BLM	Percent of Depressed on FS/BLM	Sensitive to FS/BLM Land Uses
Bulltrout	45	13	55	95	82	Yes
Westslope cutthroat	85	25	44	94	65	Yes
Yellowstone cutthroat	66	35	19	70	46	Yes
Redband	69	22	8	56	58	Yes
Steelhead	46	1	9	70	61	Yes
Stream-type chinook	28	<1	50	88	77	Yes
Ocean-type chinook	30	15	0	20	25	minor influence

Conserving the remaining watersheds and habitats that have high intrinsic value or condition for aquatic species is the key to maintaining system integrity. Focus areas include those areas supporting strongholds for one or multiple species, areas of high genetic integrity or fringe distributions, and areas that support narrowly distributed endemic or listed species. For example, many narrowly distributed endemic species are associated with small isolated systems of the interior Oregon Lakes and Klamath basins and illustrate the special significance of these areas. Reconnecting and expanding the mosaic of strongholds for widely distributed species such as the key salmonids would help improve system integrity. For wide-ranging fishes such as the salmon, steelhead, and other migratory trouts, this includes protection of water quality and passage in migratory corridors as well as protection of spawning and rearing areas. Conservation and restoration of important habitats for key salmonids could provide habitat for associated species and will sustain important processes that influence structure and function within these systems.

Restoring or maintaining the integrity of migration corridors will be challenging. Restoration and management of watersheds on Federal lands only will not be sufficient. River corridors surrounded largely by private lands are a particularly important part of fish habitat networks. The connections and habitat provided by larger river systems are critical to the maintenance of anadromous populations. The construction of dams and reservoirs and their complex effects on migration is viewed as the single greatest threat to the persistence of salmon and steelhead in the upper basins. Although much of the highest-quality habitat for these anadromous fish probably remains in the Central Idaho Mountains, no strong populations persist there due largely to passage mortality in migration corridors. These corridors provide a critical link that maintains the complex life histories of other species as well. For example, there are non-anadromous species that retain migratory life-history patterns. Species such as bull, redband, Yellowstone cutthroat, and westslope cutthroat trout may move repeatedly between small rivers and headwater streams used for spawning and initial rearing and large rivers or lakes used for subadult rearing, overwintering, or seasonal foraging.

Aquatic community composition has been influenced by the introduction of non-native species and hatchery-propagated native species. Non-native species containment would also increase system integrity. We found large numbers of introduced species throughout all major river systems. The changes are most severe in the

warmer mainstems, but higher-elevation tributaries are also affected. Land management agencies could cooperatively work with State fishery management agencies to reduce or eliminate stocking of non-native and hatchery-reared fish in areas capable of supporting self-sustaining native species. Containing non-natives will provide benefits that go beyond system integrity.

Intensively Managed Areas

While watershed protection is an effective management approach, evidence suggests that system integrity can be maintained in some intensively managed areas. We found robust fish populations in areas with minimal disturbance. We also found that intensive land use did not necessarily eliminate all strong populations or areas with high integrity. We could not discern, however, whether intensively managed areas with high integrity are anomalies, regions where the effects on streams lag behind the changes on land, or are areas where intensive management and fish can coexist. A more careful examination of these areas may provide useful guidance for future management of disturbance in important watersheds.

Ecosystem Management and Fishes

Six major issues involved with ecosystem management and fishes were examined: 1) catastrophic wildfire and active forest restoration; 2) the role of federal land management in managing for anadromous fishes; 3) the effect of roads on sedimentation and fishes; 4) the function of special emphasis watersheds relative to unroaded areas; 5) subbasin classification to provide a spatially explicit description of aquatic needs and opportunities; and 6) riparian habitat conservation area ecological requirements.

Wildfire and Forest Restoration

Refounding of populations through dispersal from local refuges and through complex life history and overlapping generations are two primary factors important in fish population recovery following a large wildfire. Spatially diverse and complex habitats are important to both types of population recovery. Complex landscapes not only produce a mosaic of burn effects, they also create a mosaic of pre-fire stream habitat conditions that provide important refuges within the burn perimeter. That same pattern of stream habitats, the size of the watersheds, and the connection of the watersheds to a larger river basin are likely important in the full expression of life history. Strong, well-distributed populations appear to have a high potential for recovery following intense wildfires. Depressed populations inhabiting marginal or degraded habitat may lack the resiliency to adequately deal with catastrophic disturbance.

The use of intensive forest management to reestablish more natural landscape patterns and disturbance regimes has variable risks and benefits across the landscape. However, the consequences of large fires are dependent on habitat conditions and the inherent resiliency of local populations. Risks to aquatic ecosystems from fire may be most important where they have been seriously degraded and fragmented. Watersheds that support healthy populations may be at greater risk through disruption of watershed processes and degradation of habitats caused by intensive management than through the effects of fire.

Role of Federal Land Management

There is no question that Federal land management has an effect on anadromous salmonids; however, it is not known to what extent efforts to improve and/or protect habitat will aid in the recovery of depressed populations, given the other factors affecting these fishes. With current conditions in migrant survival, many stocks are at serious risk. Rehabilitation of depressed populations cannot rely on habitat improvement alone. It requires a concerted effort to address causes of mortality in all life stages. These include freshwater spawning and rearing, juvenile migration, ocean survival, and adult migration. Thus, to realize the benefits of improved migration and ocean survival, good-quality freshwater habitats and populations

must be maintained, and the distribution of high-quality spawning and early rearing habitats must increase. Improved federal land management is crucial to this task.

Roads and Associated Activity

Roads contribute to the disruption of hydrologic function and increase sediment delivery to streams. Roads also provide access, and the activities that accompany access magnify their negative effects on aquatic habitats. Activities associated with roads include fishing, recreation, timber harvest, livestock grazing, and agriculture. Roads also provide avenues for stocking non-native fishes. Unfortunately, we do not have adequate broad-scale information on many of these attendant effects to accurately identify their component contributions. Thus we are forced to use roads as a catch-all indicator of human disturbance.

The discussion of the relationship of roads to fishes often centers around three themes: 1) the belief that road-building practices have improved enough in the last decade that we should not worry about their effects on aquatic systems; 2) the legacy of past road building is so vast and road maintenance budgets so low that the problems will be with us for a long time; and 3) the belief that there is not a strong correlation between road density and fish habitat and population.

From an intensive review of the literature, we conclude that increases in sedimentation are unavoidable even using the most cautious roading methods. Roads combined with wildfires accentuate the risk from sedimentation. The amount of sediment or hydrologic alteration from roads that streams can tolerate before there is a negative response is not well known. It is not fully known which causes greater risk to aquatic systems: building roads to reduce fire risk or realizing the potential risk of fire. More research is needed in this area.

The ability of the Forest Service and Bureau of Land Management to conduct road maintenance has been sharply reduced because of declining budgets. This is resulting in progressive degradation of road drainage structures and a potential increase in erosion. Most problems are with older roads that are located in sensitive terrain and roads that have been essentially abandoned, but are not adequately configured for long-term drainage. Given the magnitude of the area of federal forests with moderate to high road densities, the job of road maintenance will be expensive. Most road networks have not been inventoried to determine influence on riparian or aquatic resource goals and objectives.

We conducted two analyses examining the correlation of roads to habitat and fish population status. Each of these analyses support the general conclusion that increasing road density correlates with declining aquatic habitat conditions and aquatic integrity. Our results clearly show that increasing road densities (combined with the activities associated with roads) and their attendant effects are associated with declines in the status of four non-anadromous salmonid species. Those species are less likely to use moderate to highly roaded areas for spawning and rearing, and if found are less likely to be at strong population levels. There is a consistent and unmistakable pattern based on empirical analysis of thousands of combinations of known species status and subwatershed conditions. The analysis is limited primarily to forested lands managed by the Forest Service and Bureau of Land Management.

Special Emphasis Watersheds

We examined several efforts to identify special emphasis watersheds for conservation of aquatic resources and ecosystem function in the Basin in order to address whether habitat criteria or population presence and status are better indicators for such special fish emphasis watersheds. We used fish population strength to identify the best remaining habitats within the Basin by focusing on subwatersheds with designated strong populations of seven key salmonids. This approach has the distinct advantage of recognizing the biological building blocks necessary to maintain and rehabilitate fish

populations in the Basin. The population status watershed approach incorporates excellent habitat, strong populations, and unroaded areas.

Designated wilderness and potentially unroaded areas are important anchors for strongholds throughout the Basin. More than 8 million hectares (27%) of Forest Service and BLM lands in the Basin contain strongholds (40% of Forest Service and 4% of BLM). These stronghold subwatersheds contain large areas of unroaded land (about 4.7 million hectares), averaging 58 percent of the area of an individual subwatershed.

Subbasin Classification

We developed a simple classification of subbasins (approximate area of 280,000 hectares) throughout the Basin. The classification scheme provides a spatially explicit description of aquatic issues, needs, and opportunities that can be associated with similar descriptions for terrestrial ecosystems. We grouped the subbasins into three classes based on contiguous, well-connected subwatersheds with high aquatic integrity and strong populations. The categories range from the best connected to the most isolated and fragmented populations with few or no strongholds within a subbasin.

RHCA Ecological Requirements

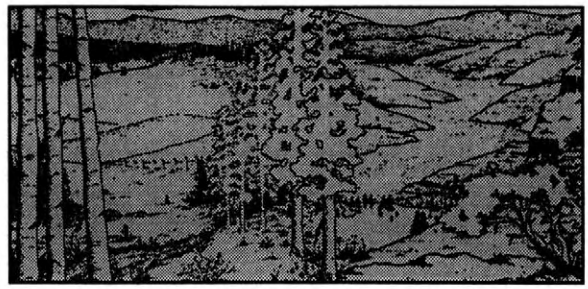
We examined recent literature to look at the sufficiency of interim riparian habitat conservation areas (RHCAs) to maintain ecological functions and prevent cumulative effects. Forest plans and forest practice rules regulate two major features of RHCA: 1) width; and 2) the type and amount of activities that can take place within them. By design, a RHCA is to be wide enough to maintain ecological function at the small watershed level and limit disturbance near streams. Interim RHCAs in the range of anadromous fishes and bull trout are prescribed at 90-meter minimum widths for fish-bearing streams in order to maintain stream function and prevent sediment inputs from non-channelized sources. A review of the literature indicates that this width is likely to be sufficient to provide for most riparian functions with a margin for error depending on the intensity and extent of activities within a RHCA.

The likelihood of disturbance resulting in discernable in-stream effects increases as adjacent slopes become steeper. Thus, greater protective measures to protect or rehabilitate riparian function and structure on steeper slopes may be required to prevent or reduce in-stream effects. The specific width necessary to protect a given stream and riparian area structure and function can be determined based on watershed and site-specific analysis.

Taken in aggregate, the standards for management of stream and riparian systems on forest lands are more restrictive and ecologically more effective than requirements for riparian areas where agriculture and urban or industrial land uses are dominant. No state within the Basin has enacted an agricultural practices act explicitly protecting riparian vegetation. Improved protection of riparian areas in agricultural lands is essential if salmon and many native fishes are to survive in the long term.

Research Needs

Our collective knowledge of status, distribution, and habitats for fishes is incomplete. The classifications of status were incomplete for 12 percent to 15 percent of the historic range for anadromous key salmonids, and 33 percent to 67 percent of the presumed range for non-anadromous key salmonids. Classification of status was most complete for chinook salmon and least complete for redband trout. Our knowledge reflects the historical focus of fish-management and research agencies on production and yield, recreational fishing opportunity, and high-profile species rather than on biotic integrity or species conservation. Limited information is available for most fishes. Sampling methodologies are poorly developed, inventories are incomplete, and reference standards are virtually nonexistent.



The development of consistent, reliable, large-scale species inventories and databases will be critical for long-term management and evaluation of aquatic ecosystems. Continued research to define critical habitat requirements and predict distributions at multiple scales will be a key element in understanding both current and potential distributions.

Many of the 38 special concern taxa are poorly understood and in need of study and rigorous monitoring efforts. Habitat and population monitoring is essential if management is to respond to factors threatening the persistence of the narrowly distributed endemics.

Evaluation of the roles of riparian buffer zones and corridors of variable structure, size, shape, and connectivity will improve integrated aquatic-land management. Field experiments can be developed to assess the potential role of riparian management areas in watershed management. These experiments may answer fundamental questions necessary for knowledgeable watershed management. They may provide information on the spatial dimensions (that is, width, length, depth, space, and continuity) necessary to achieve single and multiple ecological and/or social objectives and on how well these areas function through time.

It is important to evaluate the role of hydrologic and geomorphic disturbance from extreme events on the biological structure and function of streams, lakes, and riparian management areas. Three types of studies can contribute to this evaluation. First, field surveys are needed to assess the effect of historical events such as fires and large floods. Second, intensive, opportunistic surveys could be undertaken during and following such rare events. Third, the resilience of riparian and aquatic ecosystems to changes in the magnitude and frequency of extreme events could be tested using human-caused events (such as regulating levels of dams and reservoirs).

EXECUTIVE SUMMARY- TERRESTRIAL ECOLOGY OF THE BASIN

A first-ever catalogue of biodiversity of the Basin revealed diverse communities of plants, invertebrates, and vertebrates. However, many species groups are largely unstudied. Over 43,000 species of macro-organisms are estimated to occur within the assessment area and 17,186 species are known to occur. Micro-organisms, critical to ecosystem health and function, probably tally at least several hundred thousand species. This biodiversity results from the wide variety of habitats, topographic conditions, and prehistoric events within the study area. For this assessment we evaluated 14,028 species of macro-organisms. We explicitly included 1,339 individual species and 143 species groups in a database on species-environment relations (SER). We also identified 296 species (excluding fish) that are of particular interest to American Indian tribes.

Some 264 taxa (species, subspecies, or fish stocks) have Federal listing status (table 1.6). Among non-fish taxa, these include 184 Category 2 Candidate, 31 Category 1 candidate, 11 endangered, 6 threatened taxa, and 1 taxon federally proposed as endangered. The Forest Service and Bureau of Land Management list 538 species (excluding fish) as sensitive. Some of the threatened and endangered species and many of the additional species of potential conservation concern are dependent on environmental or habitat components not evaluated at the broad scale.

We do not project species' viability in this assessment. Rather, this assessment sets the stage and provides base information including species distribution, habitats and key environmental correlates, and management actions and effects, as a basis for subsequent viability evaluation. Species' viability under various planning alternatives is presented in another document.

Our work provides an ecosystem context for managing and restoring habitats and environments for terrestrial species and communities. We provide a classification system for environmental correlates and for ecological functions of species and identify functional species groups based on their ecological roles. Although the FS and BLM are charged primarily with habitat management, knowledge of species' ecological roles and the dynamics of plant and animal communities provides a stronger knowledge base. It creates an ecological foundation for ecosystem management. We discuss selection of bioindicators for monitoring environmental changes and for assessing grassland deterioration problems. We examine possible actions for mitigation and restoration.

Land managers will probably be most interested in the following products: (a) lists of habitats and associated species with the greatest declines in area or distribution since historic times; (b) Species-Environment Relations (SER) databases listing species by habitats and ecological functions. The databases are used to determine the potential effects of ecosystem management activities. They can be used to proactively craft activities which emphasize or restore specific habitats or functions; (c) over 520 species distribution GIS maps and additional maps showing areas of high biodiversity and species rarity and endemism; and (d) descriptions of how fungi, lichens, bryophytes, and invertebrates have key ecological roles in maintaining ecosystem health, long-term productivity, and sustainable resource use.

Table 1.6— Numbers of taxa (species, subspecies, fish stocks) by Federal listing status, extirpated, and of special interest to American Indian tribes. Listing status classes: C1 = Category 1 candidate ; C2 = Category 2 candidate; Forest Service sensitive (in at least one state within the assessment area); Bureau of Land Management sensitive (in at least one state within the assessment area); Joint FS/BLM sensitive = same species listed by both FS and BLM as sensitive; Tribal = species identified by the ICBEMP Science Integration Team as of particular interest to American Indian tribes.

Species at Risk

The Assessment contains a complete catalogue of all federally listed threatened, endangered, and candidate species. The database also includes information on The Nature Conservancy and Heritage Program rare plant categories, and state- and agency-specific listing categories of all species. Summaries of conservation plans and useful management actions for federally listed species are provided.

The assessment also identifies a number of additional taxa, especially plants and invertebrates, worthy of additional attention. These include: 394 fungi species; 40 functional groups of lichen species; sundry types of microbiotic crusts (not classified); at least 400 apparently regionally rare bryophyte species; 280 individual vascular plant species and 82 rare plant communities; 144 rare and endemic invertebrates (gastropods and insects); and various vertebrates. Among the vertebrates are the more aquatic-dwelling amphibians, reptiles susceptible to ground-disturbing management activities, and birds and mammals associated with habitats that are now scarce, declining, or increasingly fragmented. These include native grasslands, sagebrush, and old low- and mid-elevation forests. Basic inventories are needed for many of these species to determine their true rarity.

We do not advocate a species-by-species approach to management of all such species at risk. Many of the species on these lists can be assessed in groups. Inventories, where desired, could aim at gathering information for many species simultaneously, and management guidelines could address their collective habitat and environmental requirements or locations of joint occurrence.

Species Environment Relations

Native grasslands (Fescue bunchgrass, *Agropyron* bunchgrass), shrublands (big sagebrush), and old single-story and multi-story stages of many forest types, especially lower montane forests, have declined in total area and shifted in distribution since historical times. Most declines have occurred on Federal lands, although non-Federal lands have also experienced declines. Many species of plants and allies, invertebrates, and vertebrates are associated with these types. Vertebrate species associated with the decline of old-growth forests included primary cavity excavators and species with large home ranges. Other vegetation types, including young successional stages of forests, conifer-encroached sagebrush and disturbed riparian conditions, have increased in total area and distribution since historical times.

Major ecological species functions are summarized from the SER databases. Understanding functions is critical to crafting appropriate ecosystem management guidelines; the fate of individual species is only one facet of terrestrial ecology conservation. The major ecological functions we addressed were: species contributing to major biomass; herbivory; nutrient cycling relations; interspecies relations; soil productivity; wood decomposition; and water quality. As a land management tool, Federal managers will probably find these ecological/functional species groupings more useful than a list of individual keystone species.

Probably no vertebrate became regionally extinct in historical times; information on other taxa is lacking. Small-bodied, less widely-vagile species may be at greater risk for declines or local extirpations. Range edges are important for species conservation. Using the SER model, we identified species closely associated with conditions affected by management including: forest canopy; mistletoe brooms; dead parts of live trees; trees with exfoliated bark; snags; down wood; litter and duff; fire processes and insect outbreaks; recreation; roads; and trails. This information may be useful for managers predicting potential activity effects. The information will help identify specific conditions for the conservation of species functional groups.

Fungi

Fungal flora and management activities, effects on fungi are poorly known. Some species are important to recreational and commercial gatherers. Many kinds of fungi occur, including species with narrow distributions, species that fruit after fire, species

that fruit in dung, and species that are mychorrhizal and saprophytic and thus depend on host plants. Fungi conservation can include protection of type localities in small, site-specific mycological preserves and further study of species biology and ecology.

Lichens

Lichens play key ecological roles in ecosystems. These include contributing mass and nutrients to litter and duff, increasing canopy and soil moisture-holding capacity, fixing atmospheric nitrogen, serving as food for animals, and acting as bioindicators for air quality. They may also have significance for some American Indian tribes. The 736 lichen species were divided into 40 functional groups based on ecological relationships. The groups occur on four main substrates: dead organic matter, corticate and decorticate wood, rock, and soil. Lichens are major components of native rangelands and provide critical soil functions. They have been threatened by exotic grasses, increased fire frequency, rangeland conversion, and livestock trampling. One lichen, *Texosporium sancti-jacobi*, is listed as a candidate (C2) species. Providing clumps of old trees and uneven-aged stands for their legacy of lichens can improve lichen conservation. Basic lichen surveys and studies of management effects are needed to supplement our poor knowledge base.

Bryophytes

Most bryophytes have wide Arctic-alpine and boreal distributions. Others are coastal and north Pacific or occur in arid environments as part of soil crusts. Four taxa are endemic to the assessment area. Eleven ecological groups of bryophytes were identified based on common use of substrates. Changes in water quality affect aquatic submerged and wet-rock species. Forest canopy openings often adversely affect mycorrhizal species associated with decaying wood and forest humus and duff. Commercial collection of bryophytes may affect some of the humus and duff species. Other species in bogs, fens, and other environments are poorly studied. Dry soil species are critical to soil protection. Many species, at least 400, may be regionally rare. An inventory would help determine status, especially bryophytes in arid habitats, peatlands, floodplains, geothermal areas, isolated canyons, on calcareous rocks, and mineralized deposits. Bryophyte conservation can include training for identification, adding bryophyte identification to field vegetation plot data, and inventorying bryophytes in protected areas.

Vascular Plants

Vascular plants in the assessment area number at least 8,000 species, which include at least 154 local or regional endemics. The diversity comes from complex biophysical environments along gradients of elevation, bedrock and soils, temperature, and moisture. Native plant communities have declined significantly in the assessment area, prompting concerns about future conservation of rare species and rare plant communities. Of particular concern are communities affected by grazing, exotic species introduction, and timber harvest. Examples include bunchgrass grasslands of the Palouse region and low elevation cedar/hemlock old forests. The sustained harvestability of some 205 plant taxa are of concern to American Indians. Conservation measures can include monitoring rare species and plant communities; off-site collection of pollen, seeds, and rare plants; and protecting of key areas of high species rarity, endemism, and diversity.

Invertebrates

No terrestrial invertebrate species is listed as threatened, endangered, or C1 candidate (although five aquatic invertebrates are threatened or endangered). Thirty-eight terrestrial invertebrates are C2 candidate species. The FS does not list any as sensitive species and the BLM lists 25. Some 95 terrestrial mollusks would benefit from conservation attention singly or as groups; many of these are confined to calcareous substrates. Invertebrates are critical components of many ecosystem functions including detritivory and nutrient cycling. We identified 104 rare and endemic species that bear further watching. Functional roles of invertebrates include: detritivory and nutrient cycling; maintaining soil structure, chemistry, and productivity;

wood decomposition; herbivory; pathogenic effects on other organisms; and control of disease-causing organisms. Invertebrates can make excellent bioindicators of soil and vegetation health.

Most arthropods are poorly known; many are unnamed. Arthropod predators may control other invertebrate populations including some defoliator pests. They require a mix of habitat types, down wood, and vegetation substrates. Invertebrate pollinators are critical to maintaining the flora. In grasslands and forests, species groups, particularly herbivores, are important links in food webs and affect vegetation succession. A few are agricultural or forestry pests. Fire and changes in soil chemistry directly affect invertebrates, especially in range and forest conditions altered from historic structures. Other concerns are mechanical and livestock compaction and soil mixing. Other activities potentially harmful to desirable invertebrates include overgrazing, some recreation, loss of sphagnum bogs, exotic plants or arthropods, and pesticide use. Providing a diversity of habitats, maintaining soil structure and soil chemistry, and preventing or eradicating exotic species could enhance conservation of invertebrate species.

Vertebrates

Amphibians require water or moist environments, are susceptible to exotic species, and are associated more with substrates such as down wood or talus than with vegetation types or stages. Amphibians transfer nutrients from aquatic to terrestrial environments, are prey for predators, and contribute major biomass in forest ecosystems. Studies are needed to determine the effects of water quality changes, canopy closure, pesticides, livestock grazing, eutrophication, and ultraviolet radiation on amphibians and on their dispersal and distribution. Reptile distribution is more closely associated with elevation, aspect, and substrate than with vegetation. Reptiles are susceptible to dams, off-road vehicle use, loss of wetlands, livestock grazing, and fire suppression. Better survey techniques for reptiles are needed. Birds are susceptible to management-induced changes in vegetation, especially historic declines in old, single-story, interior ponderosa pine forests and grasslands dominated by *Agropyron* bunchgrass. In particular, impacts to grasslands have caused declines in Columbian sharp-tailed grouse numbers. Neotropical migrants would benefit from conservation and restoration of riparian, old forest, shrub-steppe, grassland, and juniper habitats. Mammalian population or habitat declines include some bat species and predators. Some 42 vertebrates are listed as endangered, threatened, or C2 candidate. Few locations still contain all top predators.

Biogeography, Endemism, and Biodiversity

Broad-scale biogeography of species is poorly studied in the assessment area. We identified some species closely associated with some of the nine landform classes. Distributions of local endemics can result from contracted ranges due to habitat loss or extirpations, overall scarcity of suitable environments, or other factors. Apparent peripheral, disjunct, and scattered distributions of some species may be an artifact of the location and size of the area of interest. Species such as boreal owl appear as disjunct populations because of breaks in distributions of suitable environments or incomplete sampling. Smaller and more isolated disjunct populations are likely to be more susceptible to local declines or extinctions. Locally endemic species or subspecies are highly habitat-specific, such as Coeur d'Alene salamander. Most Ecological Reporting Units had at least some unique species, although many species overlapped several ERUs. Some species are closely associated with single biophysical factors, although many species are likely correlated with multiple factors.

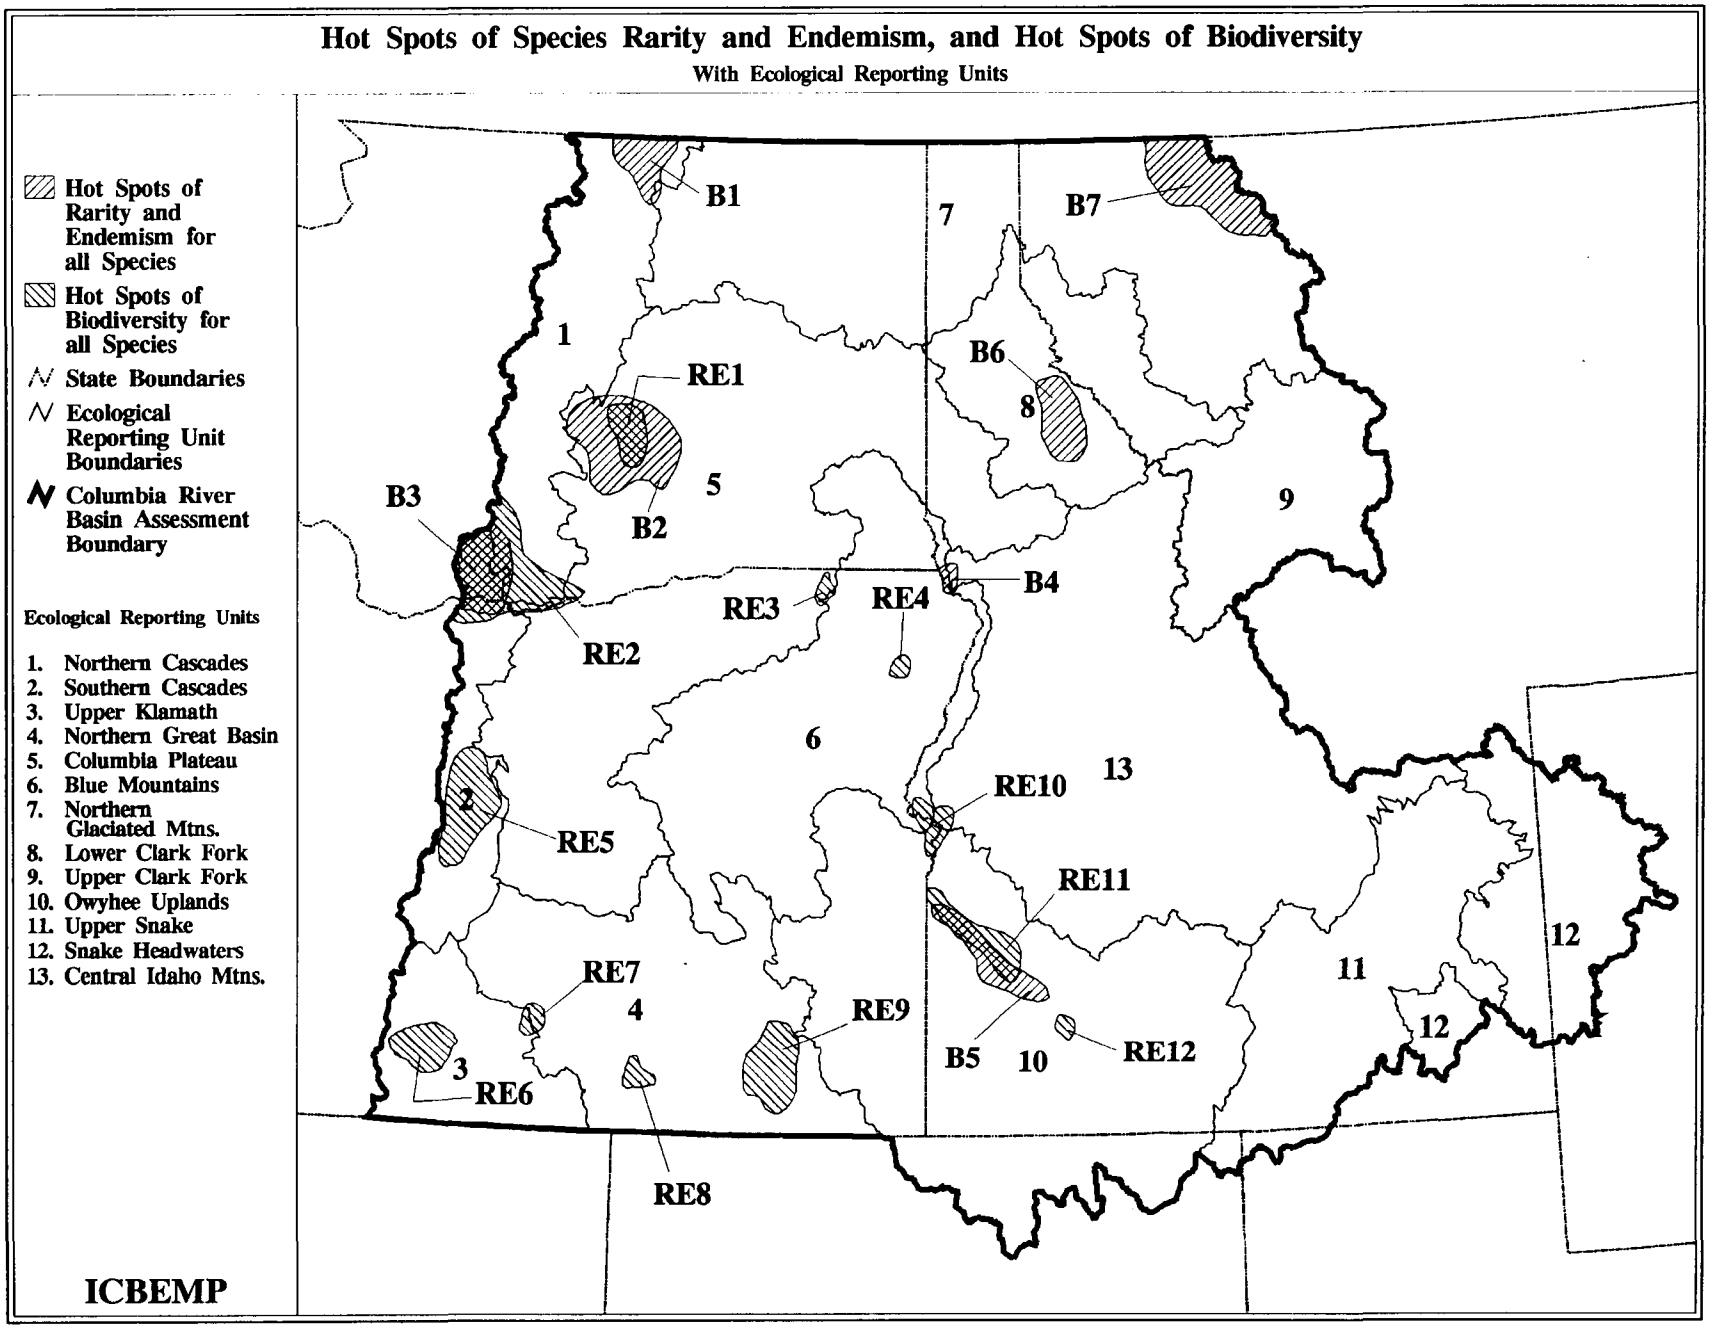
We mapped centers of concentration for (1) species rarity and endemism and (2) high biodiversity. Centers of concentration were mapped separately for plants and for animals. Locations with several centers of concentration for these two types defined smaller "hot spots" for plants and animals combined (map 1.9). We identified 12 hot spots of species rarity and endemism and seven hot spots of high biodiversity. Additional hot spots may be identified at finer levels of geographic resolution

than we used in this project. Hot spots included southwestern Oregon, the Snake River, the Columbia River Gorge, and desert steppe in central and southern Washington.

Environmental condition maintenance within these hot spots can be one aspect of a broader biodiversity conservation strategy. Other aspects can address protecting type locations of rare fungi, lichens, bryophytes, and vascular plants; protecting unique plant communities; *ex situ* plant conservation measures; providing for plant and animal species associated with rare or declining vegetation communities (especially native grasslands, native shrublands, and old-growth forests); ensuring adequate habitat for plant and animal species of interest to American Indian tribes; and conserving locations still containing all top vertebrate carnivores.

Natural areas on Federal lands total 11.72 million hectares in 26 land allocation categories. The size of existing natural areas might be suitable for supporting at least small populations of at least 70 percent of vertebrate species. Natural areas of various kinds might be "realigned" or enhanced to better coincide with hot spots of species rarity and endemism and hot spots of high biodiversity. Criteria for selecting new natural areas might be based on consistent ecological themes.

Maintaining Ecological Integrity of Terrestrial Ecosystems



Our findings suggest some measures for helping to maintain terrestrial ecosystem integrity. (1) To conserve biodiversity, some realignment of natural areas may better represent ecosystems and provide for rare and endemic species. Also, conservation measures can be considered for at least 12 "hot spots" of species rarity, endemism, and richness. The full array of historic vegetation conditions in the Basin can be provided. (2) For maintaining long-term terrestrial ecosystem productivity, the ecological roles of soil micro-organisms could be better studied and incorporated into management. (Also helpful would be providing environments for unique assemblages of species and functional groups of species.) (3) For maintaining long-term evolutionary potential, populations of species with disjunct distributions could be provided for, as could populations of locally and regionally endemic species and locally endemic subspecies. Protection could be afforded for rare plant type localities. Both in-field and off-site rare plant conservation measures could be instituted.

Additional Work

Some policy questions and issues cannot be addressed at the broad regional scale. Additional work is necessary for (1) further describing historical trends and current conditions and threats for species at finer scales of resolution than this current study affords, and (2) collecting basic scientific knowledge on life history, ecology, and distribution of many species.

Much basic scientific information on species could be gathered through inventories of many fungi, lichens, bryophytes, and rare plants. Selected rare plant communities could be monitored. Basic inventories and taxonomy studies of invertebrates could be conducted, along with studies on basic ecology, biology, and ecological roles of many plants and most invertebrates. Early warning indicators (bioindicators) of potentially degrading ecosystem health could be identified and used cost-effectively. Potentially useful bioindicators include some soil crusts, micro-organisms, arthropod herbivores, fungi, lichens, and bryophytes.

About 86 percent of arthropods, 67 percent of fungi, and 51 percent of mollusk species estimated to occur in the assessment area have not been studied, surveyed, or, in some cases, even identified. Much inventory and basic systematics work remains to be done on these groups. Soil micro-organism groups and microbiotic (soil) crusts within the assessment area are poorly known and little studied (critical for maintaining soil productivity). They are critical for maintaining soil productivity.

Map 1.9—Hot spots of species rarity and endemism, and hot spots of biodiversity.

EXECUTIVE SUMMARY-ECONOMIC ASSESSMENT OF THE BASIN

A fundamental tenet of land stewardship is for managers to direct and maintain ecosystems to fulfill the objectives of the owners. For the Forest Service and Bureau of Land Management, providing a broad array of ecosystem goods, functions, and conditions is appropriate. It is required by law. In order to implement ecosystem management, these agencies have a threefold economic challenge: to produce the bundle of ecosystem goods, functions, and conditions that society wants (economic efficiency), whose distribution of benefits is according to societal wishes (equity), without adversely affecting economic activity. We address each of these issues in turn. At the end, we briefly characterize the economic issues related to fish, minerals, range, recreation, and timber.

Economic Efficiency

Under current management, FS and BLM lands in the Basin provide society with a wide array of benefits. The current and future importance of the benefits (that could be measured and valued) is shown in table 1.7. This table shows that among outputs and conditions we evaluated, unroaded areas on FS- and BLM-administered lands are highly valued. Unroaded areas will continue to be valued through the year 2045, although their relative importance may diminish. The relative importance of other outputs will probably shift over time. Existence values aside, the three most highly ranked uses for FS- and BLM-administered lands in the Basin are currently timber, fishing, and hunting. Our projections indicate that by the year 2045 the three most highly valued uses will be motor viewing, day use, and trail use. This suggests that the FS and BLM will face a fundamental shift in their constituencies. It also suggests that the objectives of land management activities might be different in the future. Currently, there is lower relative importance placed on wildlife viewing, motor and nonmotor boating, range, off-road vehicle (ORV) use, and snowmobiling provided by FS- and BLM-administered lands. These activities are included in the "other" category in table 1.7.

Given their differences in natural resource endowments, road infrastructure, unroaded areas, proximity to population centers, and residents' age and income characteristics, each ERU is predicted to provide society with a different bundle of benefits. In the coming decades, most ERUs will probably experience a reordering of priorities, generally toward recreation.

The institutional framework and societal desires from public land stewardship continuously evolve. During the course of U.S. history, major land management themes have changed from privatization (1800-1891), to conservation and scientific management (1891-1945), to commodity production (1945-1960), to increasingly complex and contentious demands (1960-present). Today, the agencies are faced with attempting to balance these traditional issues with demands for ecosystem health and fire management. Society's objectives for public land stewardship will likely continue to change.

Table 1.7— The relative importance of some outputs from FS- and BLM-administered lands in the Basin, for the years 1995 and 2045.

Activity	1995 Value	2045 Value
	Percent	
Camping	3.45	4.40
Day Use	5.28	8.11
Fishing	9.88	6.64
Hunting	9.48	6.31
Motor viewing	1.88	9.46
Timber	11.49	5.38
Trail Use	3.28	6.85
Existence value of unroaded areas	46.86	41.43
Winter Sports	5.05	5.70
Other	3.35	5.72
Total	100.00	100.00

Broad indicators suggest we are sustaining forest acreage and inventory at the Basin level. Recreational impacts coupled with Christmas tree harvest, firewood gathering, and mushroom and berry picking have created a growing problem. Because these valuable resources are available to the public at little or no cost, there is little incentive for harvesters to conserve these resources. The increases in human population predicted for the Northwest suggest that demands on ecosystems and public resources will continue to increase. Establishing a fee system for recreation and special products could protect ecosystem conditions in recreational settings, maintain sustainable or harvestable levels of species, and provide new sources of revenue.

Equity

The benefits of the FS and BLM lands in the Basin are distributed widely. Consumers of beef or timber benefit, because these goods are traded in national markets. People who enjoy knowing unroaded areas exist may never visit the Basin, yet receive benefits. Millions of people, mostly residents of the Basin and the Northwest, recreate here; there is little difference in participation rates among people with different lifestyles.

About 220,000 jobs are associated with current levels of range, recreation, and timber harvest on FS and BLM lands. Range accounts for 1 percent of these jobs, recreation 87 percent, and timber 12 percent. In addition, there are jobs associated with mining special forest and range product harvest, but the number is unknown.

Federal revenue-sharing distributions to county governments are currently determined from timber sales and grazing permits. Yet some of these counties bear costs associated with recreation: infrastructure, road maintenance, and emergency services, for example. If recreation values were included, some counties could double or triple their revenues.

Economic Activity

The Basin

Agriculture and agricultural services remain economic strengths of the Basin. It has a large, diverse economy of 1.5 million jobs that is experiencing an above-average growth rate. Per capita income is growing faster than the U.S. rate, and the poverty rate is generally lower than the U.S. average. The past two decades have seen rapid population growth. What was a mature, resource-based economy has matured into a diverse economy oriented toward the technology-based, transportation, and service sectors.

We expect the general economic growth in the Basin to continue, sustained by in-migration in some areas. Growth is expected in services, finance, insurance, real estate, trade, and agricultural services. The fastest growth is expected in the service sector, which includes health, business, educational, and legal services. The manufacturing, farming, and government sectors are expected to decline over the next 50 years.

Traditional, regional economics views growth as a function of expansion in basic manufacturing industries. Contemporary challengers argue that other industries should be considered part of the economic base. Both approaches recognize that some locations have unique advantages or endowments that will attract certain types of industries. Traditionalists view these as resource endowments for extractive industries. In the contemporary schema, these include amenity or quality of life considerations that attract business, capital, and skilled labor. Our findings indicate that changes in management strategies by the FS and BLM have little effect on the economy of the Basin or its subregions from either of these two approaches. However, the effects of the agencies actions may be more pronounced at specific, local levels.

The nine regional economies in the Basin are diverse, and they are resilient to changes in FS and BLM commodity outputs. Overall, the forest products industry has had a neutral effect on recent economic growth. We found no relation between economic well-being at the county level (expressed as per capita income) and either the forest products processing facilities or the presence of timberlands—whether Federal, FS only, or private. Basin-wide, the cattle industry accounts for 29 percent of agricultural sales, but only seven percent is dependent on BLM and FS forage. Recreation accounts for 14.6 percent of the jobs in the Basin. Mining accounts for 0.5 percent, but we were unable to acquire data to determine what percent of mining jobs is attributable to FS and BLM resources.

The Boise Bureau of Economic Analysis (BEA) region is strong in agriculture, agricultural services, transportation, finance, insurance, and real estate. Twelve percent of the cattle are dependent on Federal forage. This is above the Basin average.

The Butte BEA region is the only regional economy in the Basin without a strong agricultural sector. Mining is very important there along with transportation and services.

The Idaho Falls BEA region is strong in agriculture, agricultural services, construction, and trade. Mining is important, though less so than in the Butte BEA region. Both employment attributable to recreation (30 percent), and the portion of cattle dependent on Federal forage (11 percent), are above the Basin average.

The Missoula BEA region is strong in agriculture, agricultural services, construction, and transportation. Employment attributable to recreation is 31 percent, considerably above the Basin average.

The Pendleton BEA region is strong in agriculture, agricultural services, and manufacturing. Both forest products and food processing are important components of its manufacturing sector. Economic diversity is fairly high, suggesting this economy is resilient to fluctuations in the forest products industry.

The Redmond-Bend BEA region is strong in agriculture and agricultural services. Both employment attributable to recreation (25 percent), and the portion of cattle dependent on Federal forage (9 percent), are above Basin averages. Forest products and food processing are both important components of its manufacturing sector. Like the Pendleton BEA region, economic diversity is fairly high, suggesting this economy is resilient to fluctuations in the forest products industry.

The Spokane, Tri-Cities, and Twin Falls BEA regions all are strong in agriculture and agricultural services. In addition, the Spokane BEA region is strong in trade, and the Twin Falls BEA region is strong in construction. None of these regional economies is likely to be affected by changes in FS and BLM commodity outputs.

Counties

Counties grouped according to a typology of income specialization or other characteristics exhibit different patterns of economic behavior. Those dominated by the service sector have consistently shown the highest rates of economic and population growth since 1970. They have also exhibited high resiliency, rebounding faster than other counties after the early 1980s recession. These include counties with trade-center towns, and growing recreation and tourism economies. Counties dominated by recreation or retirees have shown consistently high rates of population growth, total employment, and total personal income over the last 20 years. Between 1979 and 1989, counties dominated by manufacturing income showed the highest tendency to evolve into a different kind of economy. Many of these did so because of losses in the wood products or mining sectors.

Community Economies

Maintenance of stability in timber-dependent communities is often thought to be a FS responsibility, although the agency has no economic legal mandate. No facts document a link between sustained timber flow and community stability.

What makes timber communities less resilient than others is their tendency to be isolated and to lack economic diversity. These traits make their economies sensitive to changes in interest rates, labor productivity, consumer preferences, and national business cycles—all factors over which the FS and BLM have little influence.

In 1987, the FS identified 66 Basin communities as timber-dependent. Today, 29 exhibit characteristics indicating that their economies are sensitive to Federal timber sales. These are communities isolated from fast-growing populations and economies in the Basin. Federal policies toward such communities are more accurately viewed as political, not economic, reflecting political preferences about equity or distribution of wealth. Given that human populations in the Basin are expected to double over the next 50 years, the notion that any community may maintain stability is questionable. The more appropriate question is what attributes of communities and their economies best accommodate change.

Characterizations of Specific Resources

Fish

Through a multitude of actions of others—ocean fishing, government hydropower projects, irrigated agriculture, forestry, and grazing—the FS and BLM are managing some of the last remnants of good-quality habitat for declining fish stocks. The net result of these actions, plus habitat degradation, has been the virtual elimination of a valuable commercial fishery. It has also meant incalculable damages to the American Indians for whom salmon formed the economic, cultural, and spiritual basis of their lives. Spiritual values aside, currently the diminished Columbia Basin fishery is most valued for recreation. Much of this recreation takes place on public lands. The FS and BLM mandate to maintain habitats that support strong fish populations will probably increase as these conditions continue: human population growth and associated land-use changes, commercial fishing pressures, climatic influences on ocean habitat, and fish passage through hydropower facilities.

Minerals

There is a smaller percent of mining employment in the Basin than in the nation (0.45 percent versus 0.66 percent), but mining is very important in the six counties that account for 70 percent of the Basin's mineral production value. The Basin produces 30 percent of the Nation's silver, 12 percent of its phosphate, and 11 percent of its gold.

Metal prices, laws, and regulations will determine future mineral production rates within the Basin. The extent to which mining activity will affect public lands is difficult to know. The greatest probability for mineral development in the long term is along three geologic trend-lines which run through six ERUs. One is a northeasterly trend from southeastern Oregon into central Montana (the Owyhee, Central Idaho Mountains, and Upper Clark Fork ERUs), in which the most economically attractive targets include copper, cobalt, and large, low-grade deposits of gold and silver. In the western Northern Glaciated Mountain and North Cascades ERUs, mining for gold and silver will likely continue—underground in the short term, becoming open pit mines in the future. Considerable base metal resources lie in a northwesterly trend from southwestern Montana into northeastern Washington (Upper Clark Fork, Lower Clark Fork, and Northern Glaciated Mountains ERUs). Large-scale open-pit mining and phosphate ore processing are likely to continue in the Snake Headwaters and Upper Snake ERUs over the long term.

Range

The livestock industry's reliance on BLM and FS forage varies from 1 to 11 percent in the BEA regions, with a Basin-wide average of 7 percent. Cattle sales dependent on BLM and FS Animal Unit Months (AUMs) average 2 percent of total agricultural sales across the Basin. Many of the counties most highly reliant on Federal forage sell proportionately low numbers of cattle and calves, suggesting that the rangelands have low productivity. If current trends continue, forage use will decrease on BLM lands by 18 percent, and on FS lands by 19 percent, over the next two decades.

On average, holders of BLM or FS grazing permits run bigger, more profitable operations than those of nonpermittees. Permit acreage and AUMs are skewed toward the largest operations—a small number of individuals, corporations, and partnerships.

Recreation

FS and BLM lands in the Basin provide over 200 million recreation activity days per year, valued at $1.0 billion per year (in terms of willingness-to-pay). This is over 80 percent of the recreation value provided by all Federal lands in the Basin. At present, recreation on FS and BLM lands has a higher willingness-to-pay value than the market value of timber or range outputs in every ERU, except the Klamath Basin in which timber values will be surpassed by recreation by the year 2005. Fishing provides the greatest benefits of all activities ($300 million), followed by day use ($250 million), downhill and cross-country skiing ($230 million), hunting ($146 million), and camping ($75 million). By the year 2045, the larger and older human population will most value (in decreasing order) motor viewing, day use, trail use, fishing, and hunting.

The FS and BLM manage over 90 percent of the federally owned recreation acres in almost every ERU and Recreation Opportunity Spectrum (ROS) class in the Basin. Seventy-five percent of all activity days take place in roaded natural settings (road densities between 1.7 and 4.2 miles per square mile). Roads and access to riparian areas will be the most highly valued recreation activities for the next 50 years. If charged, recreation fees could be used to finance road maintenance, offsetting other potential decreases in road funds.

Purchases of food, equipment, lodging, transportation, licenses, and other items associated with recreation on public lands add up to significant expenditures and support some 220,000 jobs in the

Basin. The percentage of the job force supported by recreation is above the Basin average in the Idaho Falls, Missoula, and Redmond-Bend BEA regions.

A trade-off exists between access for some types of recreation and providing primitive/semi-primitive recreational settings for others. In the lower 48 states, 70 percent of the unroaded areas larger than 200,000 acres lie in the Basin. Fifty-six percent of trail use in the Basin takes place in the primitive/semi-primitive settings. Trail use is highly valued in both the Northern Cascades and Central Idaho Mountains ERUs, yet so are activities dependent on roads. An appropriate balance between roaded natural and primitive/semi-primitive settings is a question that needs further study.

Scenic integrity is another important element of high-value recreation activities such as motor viewing and day use. Managers might consider using silvicultural prescriptions that improve scenic integrity–through creating a more natural appearance and avoiding sharp edges or contrasts–particularly in ERUs such as the Northern Cascades and Central Idaho Mountains. These ERUs are expected to be highly valued for motor viewing and day use.

Special Forest and Range Products

Little is known about the special forest and range products industry in the Basin, because data on jobs and harvest are not regularly gathered. Relative to industry west of the Cascade mountains, the industry in the Basin is small but growing. It is focused around wild edible mushrooms and huckleberries. Rapid industry expansion is expected to continue. Under the present permitting system some of these species may be over-harvested.

Timber

By the year 2040, softwood timber harvest in the United States is projected to increase by 35 percent (0.6 percent per year), to 14.6 billion cubic feet. In the past five years, federal harvests have been shifting from the western to the southern states. Western states now account for 45 percent of the harvest. Timber harvest in the Basin currently accounts for 10 percent of total U.S. harvest; it has declined by 7 percent since 1986 and is expected to decline another 5 percent by the end of the decade. Public-land harvest is currently 46 percent of total harvest in the Basin.

In recent years, the number of timber jobs in Idaho and Montana has declined owing to technological improvements; no such trend exists for eastern Oregon and Washington. Based on current harvest projections, we expect modest employment declines to continue owing to related declines in timber harvest. More than 80 percent of the timber harvest in the Basin occurs in four economic areas—Spokane, Missoula, Redmond-Bend, and Pendleton; this includes both private and public timber.

Water

Current water use in the Basin (34.3 billion gallons per day) is almost entirely (93 percent) for irrigated agriculture with only minor amounts used for domestic, commercial, and industrial purposes (5 percent), and livestock (2 percent). Southern Idaho accounts for 62 percent of the water withdrawals. Projections based on per capita water use for commercial, domestic, and industrial water purposes suggests potential conflict over water use between municipalities and irrigators. Eight out of nine economic areas would have to reduce the amount of land in irrigated agriculture to meet municipal needs.

Water use and water policies while not controlled by the FS and BLM do affect land management in the Basin. For example, the listing of chinook and sockeye salmon in the Snake River has caused reconsideration of land management practices. In addition, changes in water allocation is one of the options available for ensuring the viability of fish populations. Complicating the water issue is the impact of increasing demands for water based recreational activities many of which take place on federal lands.

EXECUTIVE SUMMARY- SOCIAL ASSESSMENT OF THE BASIN

Many social, political, economic, and cultural factors and trends influence natural resource management in the Basin. In turn, natural resource management on Federal lands has indelibly shaped the social character of the people and the stability and resiliency of communities within the Basin. The social assessment documents many types of human-environment interactions to provide a better understanding of the social, cultural, and institutional context for addressing major ecosystem management policy questions.

The focus in this assessment is on eight types of interactions between people and the environment: settlement patterns; population and demographics; relevant attitudes, beliefs, and values of people who care about the Basin's physical, biological, economic, and social components; health and resiliency of small, rural communities; value of natural resource-based amenities; unique status of American Indians and their relations with the environment; role of the public in management of lands administered by the Forest Service and BLM; and the many institutions involved with natural resource management.

History of Human Settlement

The Columbia Basin has been occupied by people for at least 12,000 years. People in the original Columbia Plateau culture possessed lifeways and knowledge of the land gained over thousands of years. Specific places for fishing, hunting, and gathering became important to tribal groups for their supply of food within a yearly rhythm of seasonal rounds. The widespread use of fire by American Indians over long periods helped shape the mosaic of vegetation and associated animal communities in the interior West.

Natural resource and transportation development played critical roles in subsequent Euro-American settlement of the Basin. Mining, timber production, ranching, farming, and commercial fish harvest were important in the late 1800s; all but commercial fish harvesting are still viable industries. Communities became established in locations conducive to supporting the industries of the early era. In addition, development of communities throughout the Basin followed extension of the railroad network. In the early 1900s, road construction further opened up the area.

Society's needs and values determined choices about types of crops, dam building for hydroelectric power, road construction, natural resource and development. Throughout history, societies have had evolving needs for natural resources and evolving attitudes about the acceptability of those uses. Societal decisions about people's appropriate role in the ecosystem will continue to have far-reaching effects, both on human uses and values and the resulting effects on other ecosystem components.

Basin Population

The 1990 population in the Basin was just under three million people. The project area is sparsely populated, with a density of about 20 people per square mile, compared to the national average of 70. The counties in the Basin account for about 8 percent of the land area in the United States, but only 1.2 percent of the population. Nearly half of the population is located in 12 of the 100 counties, although just six of these (Ada and Canyon in Idaho, and Benton, Yakima, Franklin, and Spokane in Washington) are large enough to be called metropolitan counties.

The age distribution of Basin residents is similar to that of the Nation, but the Basin has a larger proportion of people under 18 years of age and a smaller proportion in the prime wage-earning years of 25 to 49. There is a larger proportion of Whites (92 percent) and American Indians (2.4 percent) than in the Nation as a whole (80 percent and 0.8 percent respectively), and a smaller proportion of Blacks (0.6 percent, compared to 12 percent nationally) and Hispanics (6.7 percent, compared to 9 percent nationally).

The Basin's population patterns over the last 45 years paralleled dramatic national changes. Between 1950 and 1970, there was a significant out-migration from rural to urban settings; over one-third of the counties in the Basin showed population losses. During the 1970s, however, most counties in the Basin reported population increases. The 1980s demonstrated a return to traditional urban migration and population patterns.

In the early 1990s, population growth again occurred throughout the Basin, with 96 percent of the counties increasing in population. The recreation counties (recreation and tourism play a large role in the economy) were particularly important centers of growth, accounting for 24 percent of the Basin's population increase.

Assumptions about migration rates affect estimates of future population growth patterns. A low estimate, already exceeded in many areas, would result in a population of about 3.5 million by year 2040; a higher estimate of 6.5 million would double the Basin's current population. Recent swings in population settlement patterns make predicting the most likely scenario difficult. Although overall population density would remain well below the national average under either scenario, there is reasonable potential for greatly increased growth. This would affect Basin resources and factor into their management.

Attitudes, Beliefs, and Values

Survey data from previous surveys and those conducted for the Interior Columbia Basin Ecosystem Management Project were used to assess people's attitudes, beliefs, and values relevant to natural resource management in the Basin. According to recent national surveys, a majority of the American public is concerned about environmental quality and believes environmental issues are a high social priority. Public support, however, could be lower than it was several years ago. Support for endangered species laws and regulations is also strong, but may have decreased slightly over the past few years. The public expressed increasing concern with seeking a balance between species protection and costs to society; this concern is especially strong among rural project-area residents. Support for salmon recovery and a willingness to accept resulting socioeconomic effects seemed stronger than support for endangered species in general. Most people perceive the major barriers to salmon recovery to be dams and over-fishing, rather than lack of suitable habitat.

Although people support the goal of healthy forests and rangelands, some are skeptical about ecosystem management and attempts to mimic natural processes. Disturbance events such as fire, insects, and disease have negative connotations for many people. Although many people understand these events occur naturally in ecosystems, many may also consider the results to constitute resource

waste. Many people claim they have yet to hear a good definition of ecosystem management. A better understanding of the concept should not be assumed to lead to greater acceptance. Many who support ecosystem management doubt that agencies have the ability or desire to implement it adequately. Some people clearly believe that ecosystem management is an excuse for agencies to continue cutting timber under the guise of forest health. Other people are simply opposed to the idea of ecosystem management for many reasons, including perceived effects on private lands; cost of restoration efforts; and perceived economic effects on individuals, communities, and broader economies.

Survey research typically found differences in opinions between residents of small rural towns and residents of larger urban areas or national publics in general. National samples tend to be stronger on environmental protection and less sympathetic to local economic effects than are local residents. This is perhaps because the national group shares more of the benefits than the costs. Small towns residents in the Pacific Northwest are less likely to favor strengthening the Federal role in resource protection. However, the opinions of these two population segments are similar on many issues, such as favoring an increased public role in public land management.

One value that has implications for ecosystem management is sense of place, which refers to how people define ecosystems and specific locations in the landscape based on their meanings and images. Place names relay traditional knowledge of land and resources by referring to plants and animals that characterize a location, actions of people at a location, spiritual role of the location, or some other important attribute of the site.

Recreation visitors develop attachments to places based on their past experiences, which are the meanings that often pass from one generation to another. People who earn their living from public land resources and opportunities typically develop close relationships to places on the land. Community residents and other social groups tend to develop collective definitions of places that are socially important.

The concept of place has not been widely or uniformly used by federal land management agencies, yet the task of defining places has proven to be a positive process for involving community residents and initiating discussion about common visions for public land management. For the purpose of public land management, place assessment best occurs at a community level, which avoids defining places with meaning only to a few individuals or places that are so broad as to have little meaning in a management context. Understanding place meanings can help ecosystem managers design actions to mitigate effects on places. It can also help resolve conflicts over uses of Federal lands.

Rural Communities

The Bureau of Census recognizes 476 communities within the Basin, including 29 cities larger than 10,000 in population and 49 Census Designated Places (locations that are unincorporated but have an identity to the local population). Of the other 398 small rural communities, 68 percent are communities of 1,500 or less, which is the smallest size class. These communities range from 22 to 1,500 in size and have an average population of 520.

Within the Basin, community health is defined by the capacity to adapt to change. This ability, termed community resiliency, is a function of economic structure, physical infrastructure, civic leadership, community cohesiveness, and amenities. The data suggested that there is no one common formula to achieving community resiliency; many strategies have proven successful. Natural resource dependent communities that have been confronted with significant challenges are among the most resilient, because they have successfully learned how to facilitate change. Other communities, however, are challenged to maintain their viability.

Population size is the single best predictor of a community's current condition and resiliency. Larger towns, which tend to have stronger economic bases, are viewed more positively by

participants in self-assessment workshops. Although larger towns also tend to have a greater degree of economic diversity than smaller towns, a greater population does not always mean a more diverse economic structure. Although people's perceptions of their community's economy are usually accurate, people tend to underestimate the diversity of their economy and overestimate the importance of traditional industries.

The community is an important level of social analysis, because communities have a large variety of sociocultural groupings that could be affected differently by ecosystem management programs and activities. Occupational groups that have identities strongly associated with natural resources are sometimes called "communities of interest." Changes in public land conditions and outputs could significantly affect the quality of people's lives regardless of their community's resiliency.

The concept of community resiliency needs further research and validation, and linkages with natural resources and other characteristics require additional exploration. Research is needed to identify and measure such concepts as resiliency and dependency and to develop systems to monitor the various interactions of communities with natural resources and public lands. This research should not focus on dependency *per se*, but on the many interactions between human communities and other ecosystem components.

Role of Public Land Amenities

Environmentally based amenities managed by the Federal Government have many social and economic roles in the Basin. The amenities contribute to the quality of life of Basin residents, attract new migrants, and provide recreational settings for residents and nonresidents. The Basin's many roadless areas provide these and many other benefits. Despite the importance of amenities, such as recreation opportunities and scenery, systems to map and inventory these values are not well integrated into current agency planning systems at ecoregion scales.

Between 1991 and 1993, an average of 200 million recreation activity days per year occurred on FS- or BLM-managed lands in the Basin. Roaded natural settings received about 75 percent of all activity days. Some activities such as trail use occurred mainly in primitive and semi-primitive areas. About 50 percent of all camping occurred in roaded natural settings. The rest was equally divided between primitive/semi-primitive and rural/urban settings. Just over six million people were estimated to have participated in wildlife-oriented activities within the four main Basin states. Wildlife viewing, photographing, and related wildlife activities were more popular than hunting and fishing in all four states.

The Basin contains 70 percent of the unroaded areas that are 200,000 acres or greater in the lower 48 states. Access to wildland-based recreation opportunities is important to the rural-oriented lifestyle of area residents and contributes to the region's identity. Landscape appearance and scenery are important environmentally based amenities, not just as settings for recreation, but as components of the Basin's image both to residents and non-residents.

The supply of scenery in the Basin was measured in terms of landscape themes and degree of scenic integrity. The five themes used to describe Basin landscapes were: naturally-evolving forest and shrub/grasslands (which cover 7 percent of the acreage in the Basin), natural-appearing forestlands (37 percent of the Basin), natural-appearing shrub/grasslands (30 percent of the Basin), agricultural lands (20 percent of the Basin), and developed areas (6 percent of the Basin).

Scenic integrity is a measure of "visual intactness." It was developed by combining data on vegetative structure, landform, and road density through a computerized program called geographic information systems (GIS). Scenic integrity was described using five categories ranging from low to very high. Less than 1 percent of the acreage administered by the Forest Service or BLM was rated as low in scenic integrity, 11 percent rated as moderately low, 38 percent as moderately high, 31 percent as high, and 14 percent as very high.

The social assessment was hampered by a lack of uniform, good quality Basin-wide data layers on important place meanings such as scenery and recreation opportunities. Although computer technology has advanced in the last few years, integration of social data lags considerably. Greater use and integration of social values into GIS technology now appears possible.

American Indians

The Indian peoples of the northern intermontane region are part of a large, loose social web strengthened by their shared experience of the Columbia Basin and surrounding ecosystems. Although the various Indian societies in the region differ in many ways, they hold a common belief about their relationship with the land and water. Their traditional subsistence economy is broad-based and includes fishing, fowling, hunting, and gathering of terrestrial and aquatic resources over very large geographic areas encompassing a diverse range of important places. Consequently, Indian peoples have accrued an encyclopedic knowledge of their environment through the millennia. Their uses and values of the land are both utilitarian and symbolic, merged in an inseparable manner.

Through various treaties, laws, and court cases, American Indians have different status, and the Federal Government relates to tribes on a government-to-government basis. Treaties and agreements established a trust relationship between Indians and the Federal Government. In these, the Federal Government became a manager or trustee over unceded remaining Indian lands and public lands. American Indians retained rights on these lands. Pre-existing rights not specifically granted to the United States through treaties or agreements, or not expressly terminated by Congress, continue to this day. The Federal Government is responsible for assisting tribes while still recognizing their sovereign rights.

Access to federally administered land is important for American Indian tribes. They need access in order to uphold their rights to resource use that are reserved under treaties. These resource uses include, but are not limited to, activities such as gathering culturally significant plant species, engaging in hunting practices, and using ceremonial sites.

The Federal Government's trust responsibilities, based on treaties and subsequent interpretations, are far reaching. They have not been satisfactorily articulated in terms that are understandable and agreeable to all involved entities. Similarly, consultation processes that direct Forest Service and BLM offices to formally interact with tribes on a regular basis have not been established. The National Environmental Policy Act and other project- or program-specific consultation requirements do not meet tribal needs. They seek meaningful consultation or participation in decisions that affect resources important to their cultures.

Role of the Public

Public participation in public land planning, implementation, and monitoring has been conducted by the Forest Service and BLM on an individual project basis for the most part. In a survey conducted for the Interior Columbia Basin Ecosystem Management Project, the public favored expansion of this role, either by acting as a full and equal partner or by serving on advisory boards. The public also expressed concern about the efficiency of public participation. Public participation was considered successful when roles of managers, scientists, and publics were clear; guidelines on public participation techniques would be helpful in developing direction and consistency.

Many public and private collaborative groups formed in the Basin over the past few years to jointly address natural resource issues. These groups typically had a balanced range of stakeholders regarding a given piece of land, natural resource, or decision. These groups provided many benefits, including opportunities for mutual learning, increased ownership in decisions, and improved

agency ability to implement plans. The groups also provided models of collaboration for use in ecosystem management strategies.

The Northwest Forest Plan created Province Advisory Committees, which was a new approach to public participation. Each of the 12 provinces, created as management units for the plan, has an advisory committee composed of Federal employees and members of the public. The plan also established Adaptive Management Areas that called for new forms of ongoing collaboration in planning, management, and monitoring public lands. A similar effort began in 1995, when the BLM and Forest Service formed Resource Advisory Councils (RACs), each covering a distinct geographic area in eastern Oregon and Washington. The RACs are designed to make recommendations to the Forest Service and BLM on ecosystem management, watershed planning, and other local or regional natural resource issues. The list of objectives for RACs includes collaborating in resource management across jurisdictions, promoting partnerships and working groups to develop regional solutions to management issues, assisting with educational efforts, sharing science and other information, and encouraging and supporting local groups to help implement ecosystem management.

Research is needed to identify measures of success, the public's response to sophisticated technology such as GIS, and the desirability of various distinct approaches at different geographic scales. Such approaches would invariably require involvement of affected stakeholder groups, because their perceptions of success are equally as important as any objective's measure. A research program to understand trends in people's attitudes, beliefs, and values regarding ecosystem management would be valuable for future planning and implementation efforts. The program would be most helpful if conducted at local, regional, and national scales.

Institutional Capacity

Society's approaches to solving collective problems involve various government agencies, as well as formalized agreements. Ecosystem management has a particular need for institutions to work effectively together, managing resources and opportunities across jurisdictional boundaries.

At the Federal level, the executive, legislative, and judicial branches have recently had an active interest in natural resource management. The BLM and Forest Service exist within a system of federal agencies that manage ecosystem components. In some cases, the agencies have missions with a narrower focus. As part of a larger Federal Government system, the BLM and Forest Service often participate in international coordination efforts to protect and maintain environmental quality. The Congress has mandated specific actions for the BLM and Forest Service over the past decade. In some cases, Congressional direction is legislated. In others, specific projects are funded through appropriations bills and attached riders.

The judicial branch is involved in environmental issues. Using litigation to address grievances is a practice that has increased markedly over the past two decades. The courts and administrative appeals process have become significant agents of change within the agencies. Survey research suggests the public would rather not rely on legislation or court cases. It prefers to work with land managers to achieve mutually desirable conditions. The public often favors increasing the role of local or state government.

Cross-jurisdictional approaches to ecosystem management may result in closer working relationships between the BLM, the Forest Service, and state and local governments. Together, the groups can identify and accomplish mutually agreeable goals. State agencies, like agencies in the Federal Government, have divided legal jurisdictions over natural resource issues. Each state within the Basin has its own unique system of agency jurisdiction and policies that relate to natural resource management. Some state agencies oversee activities on

public lands or share co-management responsibilities with Federal agencies. Although state agencies want to help develop Federal policy, they have experienced expanding responsibilities and declining budgets. Priority differences between state and Federal agencies are expected owing to distinct mandates and constituencies of each.

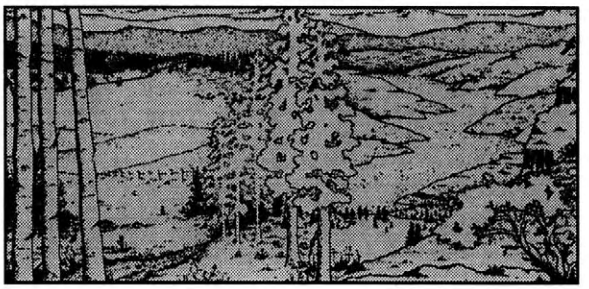
County governments are basic political organizational units that provide services to county residents. They work in conjunction with state, municipal, and other special governmental offices to support the public's needs. County governments become *de facto* land management agencies addressing many ecosystem issues through zoning ordinances, property taxation collections, and comprehensive planning responsibilities.

The relationship between county governments and the Forest Service and BLM assumed a new dimension in the Basin during the ICBEMP. The Association of Oregon Counties, the Washington Association of Counties, the Montana Association of Counties, and the Idaho Association of Counties created a new institution, the Eastside Ecosystem Coalition of Counties, to observe activities of the ICBEMP and to communicate the interests of county governments.

Land and property rights, which have a central role in ecosystem management, are highly controversial social issues that are being increasingly defined in the courts. One aspect of this debate is the idea of "takings." The idea is based on the U.S. Constitution's Fifth Amendment which states that private property shall not be taken for public use without just compensation. Advocates for private property insist that government regulations, especially those initiated for environmental protection, constitute "taking" because they reduce the opportunity for property to be freely used at the discretion of the individual. Another central issue is consolidation of private ownerships and the increased public reliance on Federal lands for access to valued opportunities.

The ability of agencies to implement ecosystem management could be challenged by the multiplicity of agencies involved, any conflicting mandates and goals, their various constituencies and legal authorities, significant cross jurisdictional boundary management questions, and short implementation time frames. Studies of previous cross-jurisdictional management efforts have shown that tolerance for change is critical. This suggests using an approach that emphasizes incremental changes and places authority for managing change with those most directly affected. Open information exchange is another key factor to accepting change. The institutions' success depends largely on learning from past practices.

There are numerous institutional challenges to implementing ecosystem management. Those identified in the social assessment include poor communication; difficulty understanding ecosystem management; laws, such as the Federal Advisory Committee Act, that may pose a challenge to some forms of desirable public participation; and aspects of BLM and Forest Service policies and procedures such as budgeting and contracting.



Human use of the Basin's natural resources is a major determinant of ecosystem conditions. Over time, human uses have changed dramatically, resulting in equally dramatic effects on the land, water, air, and other species. Human values regarding ecosystems have changed as well, as have the economic needs of an increasingly complex society.

EXECUTIVE SUMMARY- INFORMATION SYSTEM DEVELOPMENT AND DOCUMENTATION

Land use planning that is regional in scope requires tools more advanced than those typically used for landscape and resource analysis. Traditionally, maps, graphs, charts, and diagrams have been used to analyze and visualize the natural environment. Today, Geographic Information Systems (GIS) provide the tools and techniques that allow regional projects to be accomplished in a highly efficient, integrated, and accurate manner.

A GIS is especially well-suited to dealing with spatial and temporal problems (problems of dimension, space, and time). Without advanced computer technology, software, and trained and experienced individuals, the volume of data collected in support of the Interior Columbia Basin Ecosystem Management Project (ICBEMP) would have been a great burden. GIS allowed the Science Integration Team (SIT) to dynamically model and analyze living systems throughout the Basin in ways that were impractical only a decade ago.

The ICBEMP is the largest interagency database development effort undertaken by the agencies involved, covering more than 58 million hectares (over 144 million acres). The project information and technology plan was based in part on the plan developed for the Forest Ecosystem Management Assessment Team (FEMAT), but the ICBEMP team had more time and considerably more data. Work for the ICBEMP was accomplished in a number of locations. A dispersed approach to data collection and analysis was necessary owing to the cost and inefficiency of relocating all equipment and personnel to one location.

A Spatial Analysis Team was established to manage data and support the analytical needs of the ICBEMP. This team was composed of U.S. Department of the Interior Bureau of Land Management, U.S. Department of Agriculture Forest Service, and contract personnel who were located in Walla Walla, Spokane, and Wenatchee, Washington; Portland, Oregon; Missoula, Montana; and Boise and Coeur d'Alene, Idaho. The interagency group was charged with the collecting available GIS data, capturing new data, and supporting analysis for the SIT and Environmental Impact Statement (EIS) Team. The Spatial Analysis Team was also responsible for the documentation and distribution of data to project personnel, federal agencies, tribal governments, the general public, and other interested parties.

Data and Analysis

Over 170 different GIS data layers or themes were compiled or created in support of the ICBEMP Assessment and the development of the Eastside and UCRB EISs. The data layers were derived from source maps, photos, or transfer media ranging from 1:12,000 to 1:4,000,000 in scale. Some GIS layers mapped features continuously across the entire Project (Scientific Assessment and EIS area) while others covered discrete areas only (that is, subsample areas). Major data providers included individual administrative units of the FS, BLM, U.S. Fish and Wildlife Service, Environmental Protection Agency, U.S. Geological Survey,

U.S. Bureau of Mines, Bonneville Power Administration, universities, state agencies, and non-governmental organizations.

Data analysis occurred in GIS and in the database environment. GIS analysis used two data architectures: vector (lines, polygons, and points) and raster (matrices or grids). Some of the data were created in vector form (such as information captured from a map, like ownership boundaries), while other data were created in raster form (including elevation models, vegetation models, and data based on satellite imagery). Vector data were sometimes converted to raster data for the analysis process.

Information that was gathered specifically for this project (that is, it did not exist digitally before and was requested in a digital form) were either scanned or digitized once a manuscript of the data was created. These digital data sets were then attributed and brought into the GIS.

Data that were entered into the corporate data structure (master data) were plotted and inspected, and in cases of error or uncertainty, sent back to the originator for validation. Information about the data (metadata) that was compiled included information on scale and accuracy. These metadata were available to the teams and were included with any data distributed to other parties.

While analyzing management options, a variety of systems and methods were used to evaluate and analyze the existing and derived data. GIS played a key role in tying the Columbia River Basin Successional Model vegetative outputs to Management Regions, Ecological Reporting Units, and subwatersheds. Conventional databases were necessary to synthesize, summarize, and report information. Some of the databases can be spatially referenced to an existing ICBEMP GIS data layer.

Documentation, Management, and Sharing of Data

In a project such as the ICBEMP, where many cooperators shared data obtained from many sources, data documentation is a necessity. The data documentation, often referred to as metadata, is in the process of becoming standardized within the Federal Government. In 1994, Executive Order 12906 gave the Federal Geographic Data Committee (FGDC) direction to establish the National Spatial Data Infrastructure including the "technology, policies, standards, and human resources necessary to acquire, process, store, distribute, and improve utilization of geospatial data." Part of that order calls for standardized data documentation. Each agency must use the standard developed by the FGDC (FGDC Content Standard for Digital Geospatial Metadata) to document new data it collects or produces.

At the time initial planning began for the ICBEMP, the FGDC metadata standard was in early draft form. The project adopted the metadata standard previously developed by the Northwest Forest Plan effort. The resulting metadata are generally compatible but less extensive than what is described in the 1994 FGDC standard.

For management of metadata, SPUDD (Spatial Unified Data Dictionary), an Oracle database application, was used. It was developed by FS and BLM personnel for use in the Northwest Forest Plan effort and was enhanced during this project. It has the capability to store information about proposed data and document existing data sets.

It was recognized at the outset of the ICBEMP that there would be data tracking problems. This was due to the large number of people involved at various offices and to the scope of analysis that was being planned. There was a desire to make data immediately available while maintaining control so that the implications of data changes could be managed. The SPUDD was available to track

metadata for themes as they became ready for use in the ICBEMP, but the SPUDD was not able to track the changes to the data after they were entered. For this reason the Automated Tracking Manager (ATM) was designed to track GIS data and associated metadata. ATM could also recreate GIS processes. Other commercially available products were reviewed, but they were inadequate for project needs.

The ATM provided a useful tool to determine how the GIS data sets related to each other. While most GIS work was not done within the ATM, it was used as a library of processes performed. The ATM is expected to be used for continuous management of the ICBEMP GIS data and as a reference tool well into the future.

The ICBEMP began to release spatial data and maps to the public and government agencies in November 1994. Unlike previous projects, the data and maps were made available while the project data were being analyzed. A brief policy paper was prepared to provide interested individuals with the data release objectives, the processes for completing requests for data and maps, and cost information.

Information Management Recommendations

A key element for ecosystem management is the need for consistent, current, and accurate information concerning the ecological and biophysical environments across the landscape. This information is necessary at several levels of resolution. Research is needed to develop better data structures that link scales (both temporal and spatial). The collection and management of these data need to be effectively coordinated and shared between federal, state, and local agencies in order to implement ecosystem management. Federal, state, and local governments working with the public can help ensure success through their shared commitment and vision for a resource information system.

An ongoing commitment to ecosystem management and modeling will mean that federal agencies will need to reassess their individual resource inventory programs. They also need to strive for a set of interagency standards tied to ecosystem management. Currently, data are collected in many formats between and within agencies. This makes integrating data very difficult. Data need to be collected for all ownerships across ecosystems in a standardized fashion for ecological and biophysical information. Minimum data standards for vegetation, aquatic, fisheries, and terrestrial components of the landscape need to be established. Additional information in excess of the minimum required could be collected by individual agencies for their own needs. Data collected at the project level, once standardized, could be aggregated for mid-scale and broad-scale analyses.

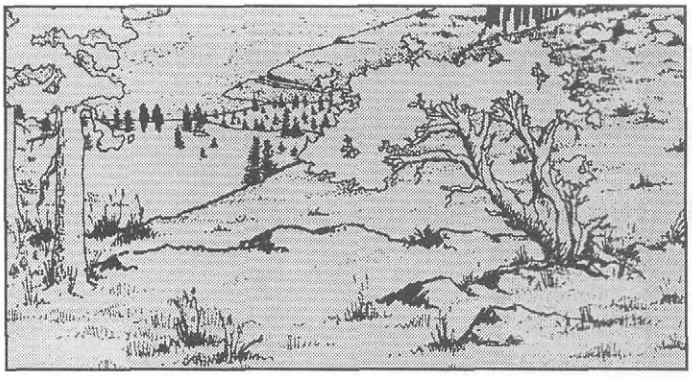
The GIS data and associated databases collected and created for use in the ICBEMP Assessment need to be managed, maintained, and shared. A central information clearinghouse could be established to support the update and implementation of FS and BLM plans. This clearinghouse could manage, distribute, and provide user support for both spatial and nonspatial data and models from the ICBEMP. Agencies could profit from the information investment of this project and develop processes for long-term resource information management.

There are several GIS data layers that need to be standardized and collected continuously across the Basin for future analyses. Theme content standardization and attributes would help build a more functional interagency data set. The following themes should be included: administrative boundaries, surface ownership administration, current land use allocations for all agencies, natural areas, wilderness, unroaded areas, and current management area categories for all agencies. Many of these themes may be used for project level work where no finer resolution data exist. In addition, many of the newly captured data sets from the ICBEMP could be maintained and improved for future analyses. These include, but are not limited

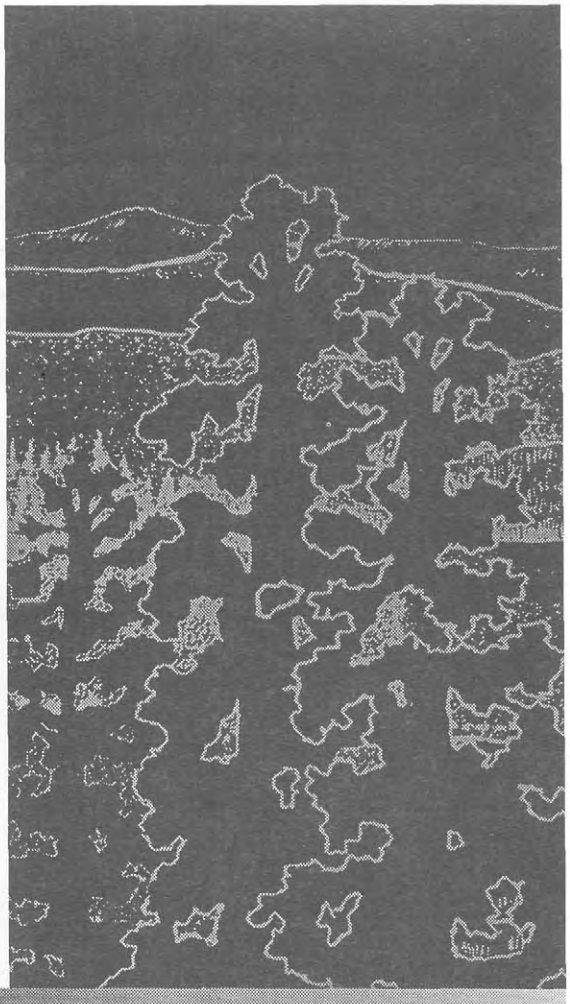
to: 6th-field hydrologic units (subwatersheds), broad-scale vegetation (1 kilometer), river reach stream inventory and databases, and the fish-related databases.

A number of GIS data sets desired by ICBEMP were not readily available nor could they be captured into GIS in a timely manner. These include: land type associations, consistently classified vegetation from satellite imagery (mid-scale vegetation), enhanced 1:100,000 stream network (until continuous 1:24,000 base data is available), and base data at 1:24,000 [digital elevation models, cultural features, streams (should be enhanced), and roads (enhanced to contain logging roads and others not on USGS base maps)]. Collected basin wide and in a standardized way, these data sets would be useful in future planning efforts.

A technology transfer program would provide field offices, other agencies, and the general public with access to and comprehension of the data, models, and information that were developed for the ICBEMP. Technology transfer is crucial for providing user support and training to the field offices over the next several years. Maintenance and periodic updates of the GIS data, databases, and models collected and developed for this project will benefit subsequent regional analyses.



Conclusion



Good progress has been made in building cooperation between agencies in order to implement ecosystem management. Our experience shows that information management is possible and critical in an interagency environment. It is hoped that the documentation of information resource management methods employed by the ICBEMP and the resulting recommendations will increase the effectiveness for future broad-scale efforts. This project highlights the importance of a long-term information resource management strategy for the implementation of ecosystem management.

BIOPHYSICAL ENVIRONMENTS OF THE BASIN

Introduction

This chapter describes important biophysical environments of the Interior Columbia Basin and those portions of the Klamath River Basin and Great Basin in Oregon (Basin). Specifically included is information about methods used in describing the environments, and descriptions of the environments' ecological processes, associated management interpretations, and general characteristics. Information is presented at multiple spatial scales for various types of biophysical environments, including geologic, geoclimatic, potential vegetation, soils, and hydrologic systems. The various levels and types of biophysical environments described in this chapter are important to the ecological assessment of the Basin for the following reasons:

- They facilitate the delineation and description of terrestrial and aquatic ecosystems that behave in a similar manner given their potential ecosystem composition, structure, and function.
- They delineate areas with similar production potentials for management.
- They provide a basis for interpretations concerning hazards and limitations to management.
- They influence (to a large degree) the natural disturbance processes that create finer-scale ecosystem patterns (for example, existing vegetation and species distributions).
- They provide a needed context for the use and development of predictive models concerning future ecosystem pattern and process relations.

The chapter is organized by six major topics, as identified and briefly described below:

Ecological Principles: This section presents a general overview of key principles that provides the foundation for a landscape ecology-based approach to assessment. The overview includes a discussion of the importance of hierarchy theory, pattern recognition, and ecological characterization to integrated ecological assessments. Biophysical environment mapping is also discussed.

Primary Biophysical Environments of the Basin: In this section is a discussion on the methods used in the mapping, as well as descriptions of selected biophysical environments within the Basin. First presented is a general description of biophysical environments, including their basic properties and uses in ecological characterization and assessment. Next described are approaches used in identifying and characterizing the geologic, geoclimatic, potential vegetation, and hydrologic settings at multiple spatial scales within the Basin.

Ecological Process Interpretations: Presented in this section are the logic and methods used in characterizing various ecological processes that are strongly influenced by the properties of biophysical environments. Analysis results are described, where appropriate, and various ecological process interpretive maps are included that display relative differences between subbasins across the Basin.

Hazard, sensitivity, and resiliency ratings are described as appropriate to the ecological processes of soil erosion, mass failure, sedimentation, peak flows, channel maintenance, and climate change.

Development of Ecological Reporting Units: This section describes the logic and methods used in the identification of integrated Ecological Reporting Units (ERUs) for the Basin. A total of 13 ERUs were delineated for the Basin based on their terrestrial and aquatic biophysical environment, as well as social/economic criteria. These delineations were used extensively by the different Science Integration Team (SIT) staff areas in the reporting of assessment results at the regional level.

Basic Ecosystem Components by Ecological Reporting Units: This section describes the geologic, edaphic, and hydrologic features of each Ecological Reporting Unit (ERU) within the Basin. These summaries provide a regional overview of the variability of important ecosystem components across the Basin. For each component, there is information concerning: existing pattern/process relations, general opportunities and limitations to management, and the effects of certain management practices on the health and resiliency of an ecosystem. Also presented is an integrated summary characterization of climate, geology, soils, and hydrology.

The characterization area needed to provide spatial context for many biophysical environments in this report was larger than the Interior Columbia Basin Ecosystem Management Project (ICBEMP) assessment area. Accordingly, the Science Integration Team (SIT) Landscape Ecology Staff identified a larger characterization area for describing the Basin's biophysical environments. The boundary of this larger characterization area followed the geoclimatic sections (Bailey 1994, McNab and Avers 1994) of the ICBEMP assessment area (map 2.1).

Hydrologic Integrity Assessment: This section describes the methods used in addressing the hydrologic integrity of the Basin. This assessment, along with other staff contributions, was used in the development of the Science Integration Team's document titled *An Integrated Scientific Assessment for Ecosystem Management in the Interior Columbia Basin and Portions of the Klamath and Great Basins* (Quigley and others 1996), referenced as the *Integrated Assessment.* Results of this hydrologic integrity assessment are presented by the six rangeland and six forest environment themes used in the SIT's *Integrated Assessment.* Also described are the primary management impacts to hydrologic function and the resiliency of subbasins within the Basin following disturbance, as well as the process used in integrating this information in the assessment of hydrologic integrity by subbasin. Narrative summaries of analysis results are included to provide a regional overview of the Basin's existing hydrologic integrity conditions.

Ecological Principles

This section presents a general overview of key ecological principles that provide the foundation for a landscape ecology-based approach to ecological assessment as described by Jensen and others (1996). The ecological principles discussed in this section were incorporated into various ecosystem characterization and analysis efforts by the Landscape Ecology Staff. They are provided to assist the readers understanding of both the conceptual relationship of the Basin's biophysical environments and their importance to ecological pattern and process prediction.

Description of Ecological Systems

Ecological systems are groups of interacting, interdependent parts (for example, species and resources) linked to each other by the exchange of energy, matter, and information. Ecological systems are considered complex because they are characterized by strong interactions between components, feedback loops, significant time and space lags, discontinuities, thresholds, and limits (Costanza and others 1993). Pattern recognition techniques, which are often used to describe ecological systems, have been used for many years by the medical and social sciences in dealing with complex systems. Because ecological systems can be

Map 2.1—Landscape ecology characterization area.

described at many different scales (Levin 1992), the spatial and temporal relations of specific ecological systems or any of their components need to be clearly defined. The scientific products generally used in conservation and land management planning are descriptions, predictions, diagnoses, and prescriptions. Describing ecological systems of interest is a routine scientific endeavor that leads to the generation of classifications and maps.

Predictions concerning future states of ecological systems under various management strategies require determination of the relations that exist between patterns and either hypothesized causal factors or agents of pattern formation. Once a correlation or a cause-effect relation between pattern and process is determined, predictions are made using:

- Summarization of data and information performed during the classification process and/or the generation of maps.
- Statistical or simulation modeling.
- A combination of these two approaches.

For ecosystem predictions to be appropriately translated into conservation or land management actions, these correlations should be based on rigorous analyses.

Hierarchy Theory

The concepts of scale and pattern are interwoven (Hutchinson 1957, Levin 1992). Complex ecosystem patterns, landscapes, and the multitude of processes that form them exist within a scaled hierarchical framework (Allen and others 1984, Allen and Starr 1982, O'Neill and others 1986). Scale dependency is important because the relationship between ecological processes, and the patterns they create, changes with spatial scale (Turner 1990). In recent years, considerable attention has been directed to describing the formal hierarchical organization of ecological systems. As applied to landscape ecology, hierarchy theory provides the framework needed to describe an ecosystem's components and their scaled relations.

Four tenets of hierarchy theory are required for an understanding of landscape patterns and their dynamics (Allen and others 1984, O'Neill and others 1996):

- The whole/part duality of systems states that every component of a system, ecological or otherwise, is a whole and a part at the same time. For example, a forest (a whole) is made up of trees (the parts). However, at larger spatial scales, the regional landscape is the whole and the forest becomes a part. The notion of whole/part duality is very important to the characterization of ecological systems.
- Patterns, processes, and their interactions can be defined at multiple spatial and temporal scales. These scales need to be clearly identified.
- There is no single scale of ecological organization that is correct for all purposes. This is an important consideration because scientists often provide information/interpretation on ecological systems at a single or limited number of scales.
- The definition of an ecological hierarchy (component patterns and processes) is dictated by the objectives of a study or planning endeavor.

Pattern Analysis

Implementation of hierarchy theory in the description of ecological systems is achieved through explicit characterization of the scaled relations that exist between the patterns of interest (for example, species and habitats) and the ecological factors that determine such patterns (that is, the agents of pattern formation) (Urban and others 1987). This type of ecosystem characterization is commonly called pattern analysis (Bourgeron and Jensen 1994) and can be illustrated using fish distributions as the ecological pattern of interest. Fish species may be visualized as exhibiting different patterns of organization (for example, individuals to metapopulations) that follow different spatial and temporal scales (fig. 2.1a). The formal definition of the hierarchical

arrangement of fish distribution patterns is important because it requires explicit statements concerning the spatial and temporal bounds of each pattern and their nesting order. Such an objective-specific exercise provides the basis for identifying pattern formation agents (Bourgeron and Jensen 1994, Urban and others 1987).

The agents of pattern formation can be organized into different hierarchies of biotic processes (fig. 2.1b), disturbance processes (fig. 2.1c), and environmental constraints (or biophysical environments) (fig. 2.1d). In this example, biotic processes important to understanding fish distribution patterns may include: behavior or physiologic adjustment at the channel unit or stream reach level, dispersal or genetic exchange at the watershed level, and speciation or extinction at the river basin level (or broader scales) (fig. 2.1b). The specific spatial and temporal relations that exist between fish distribution patterns and biotic processes are efficiently described through this type of characterization. In a similar manner, the relation between fish distribution patterns and disturbances (fig. 2.1c) and environmental constraints (fig. 2.1d) can be described if each variable is clearly specified and its spatial and temporal bounds clearly identified. At the watershed level, for example, population or guild distributions may be viewed as responding to mass wasting or flooding disturbance processes, which in turn are a function of local climate, geology, and landform environmental constraints (fig. 2.1d).

Ecosystem Characterization

Ecosystem characterization is: (1) the appropriate relation of patterns and processes at all scales of interest, and (2) the description and mapping of the entities determined through relating these patterns and processes. To match patterns and processes, ecological hierarchies such as the four tenets described in the preceding section are superimposed. Figure 2.2 illustrates this point with a terrestrial ecosystem example of subalpine fir forests in the northern Rocky Mountains. This example shows the relationship of each pattern to specific biotic processes, disturbances, and environmental constraints. For example, at the level of an individual tree in the canopy, the corresponding biotic process is tree replacement (for example, from lodgepole pine to subalpine fir), which is driven by tree fall (disturbance), which is influenced by slope and aspect (environmental constraints). At a finer scale, the pattern is the seedling, the biotic process is germination, and the environmental constraint is the snowbank on which the seed lands. Above the individual tree level, the stand becomes the whole of which the individual tree is a part. The biotic process at the stand level is succession, which integrates individual tree replacement at larger spatial and temporal scales. Stand level succession from lodgepole to subalpine fir may take over 200 years. Disturbances at this scale may include windthrow, insects or pathogens, and stand-consuming fires. Environmental constraints include slope, aspect, and landform that are commonly displayed by land type biophysical environment maps (table 2.1). The proper match of patterns to their agents of formation is important to ecosystem characterization because incorrect coupling limits the effectiveness of predicting future states of the ecological system, which in turn inhibits development of realistic land management plans.

Description of Primary Biophysical Environments

Biophysical environment maps are used to describe terrestrial or aquatic ecosystems that behave in a similar manner given their potential ecosystem composition, structure, and function (Jensen and Bourgeron 1994). Such maps are also commonly used in the delineation of environmental constraints for ecological pattern analysis. Biophysical environment maps delineate areas with similar management response potential and resource production capabilities and are constructed based on landscape components that do not display high temporal variability at a given scale of mapping (for example, regional climate, geology, or landforms).

Ecological units (Bailey and others 1994a; Cleland and others, in press; McNab and Avers 1994), land units (Zonneveld 1989), ecoregions (Omernick 1987), biogeoclimatic ecosystems (Meidinger and Pojar 1991), and land systems (Christian and Stewart 1968) are examples of biophysical environment mapping systems that delineate ecologically homogeneous environments at different spatial scales based primarily on climatic, geomorphic, and biotic criteria. Hierarchical watershed/geoclimatic maps are additional examples of biophysical environment maps that are increasingly being used in aquatic system assessment efforts (Jensen and others 1996, Maxwell and others 1995).

The ecosystem components used in developing biophysical environment maps (for example, climate, landforms, geology, or soils) do not change following most management activities; consequently, such maps provide a useful template for interpretation of data such as existing vegetation that commonly display change following management treatments. These types of data describe the "existing condition" of the landscape and are commonly associated with appropriate biophysical environment settings in determining the condition or "health" of an area. The effects of management practices on the landscape are most efficiently described by contrasting the "existing condition" of an area with other managed or unmanaged areas of similar biophysical environment settings. This process minimizes the natural variability among sites, facilitating more direct descriptions of the relations between observed landscape conditions and management treatments.

Biophysical environment maps may be delineated at different spatial scales (table 2.1) dependent on assessment needs and the types of ecological patterns and processes to be predicted. Regional, subregional, and landscape scales of biophysical environment maps were developed by the Landscape Ecology Staff for use in the assessment of the Basin. These maps included:

- Geologic Environments
- Geoclimatic Ecological Units
- Potential Vegetation Settings
- Hydrologic Environments
- Integrated Ecological Reporting Units

Ecological pattern and process relations, successional pathway dynamics, and management potential/hazard ratings were developed for these biophysical environment maps to assist various SIT and Environmental Impact Statement (EIS) team efforts. Descriptions of these biophysical environments and suggestions concerning their use and limitations in ecological assessment activities are provided in the following discussion.

Geologic Settings

Despite the fact that the geologic components of a biophysical environment do not change as a result of management activity, geologic process rates may change dramatically as a result of management. Geologic components and processes profoundly influence other ecosystem components and processes, including current and potential vegetation patterns and successional processes, as well as terrestrial and aquatic habitat and productivity, and human settlement patterns. Changes in geologic process rates due to human activity may also profoundly affect ecosystems through increased erosion, sedimentation, and toxic element release. Human activity can also improve ecological conditions through management activities that preserve or mimic natural processes. From a human perspective, some important geologic processes are catastrophic; these include volcanic eruptions and their associated effects, earthquakes, earth movements such as landslides and rockfalls, and large floods. The influence of, and interactions between, geologic processes and other ecosystem processes are described later in this chapter. The geologic environments that constrain such processes are described below.

General Description of the Geologic Environments of the Basin

The geologic components of any ecosystem can be subdivided into bedrock and surficial geologic units. Bedrock geologic units are those that are solid and underlie any unconsolidated surficial materials. These two types of units affect and interact with other ecosystem processes at many spatial and temporal scales. For example, erosion rates for most bedrock types with associated "natural" vegetative cover are generally low. Physical erosion rates for unconsolidated surficial deposits (such as alluvium, loess, or glacial till) are commonly higher than those found on bedrock units. Chemical weathering rates determine the release of rock components, such as nutrients and toxic elements, into the ecosystem. Disturbance of vegetative cover, road building, mining, agriculture, urbanization, dam building, and other human activities may profoundly increase the physical and chemical weathering rates of geologic materials. In a similar manner, such disturbances may also affect water retention or other characteristics of the rocks and soils of an area in such a way that they no longer support predisturbance vegetation cover types. Increased fluxes of sediment, toxic elements, and nutrients, or decreased water flows caused by human activities may irrevocably alter ecosystem processes and must be considered in land management planning. An understanding of both the geologic environments and geologic processes of a planning area are essential components of any ecological assessment effort.

The lithologic characteristics of rocks within the Basin are diverse, which in many cases defies simple classification of rock types by ERU. Bedrock geologic units within the Basin range in age from Precambrian rocks older than 2.7 billion years, to volcanic rocks formed during the Mt. St. Helens eruption of 1980. Rocks include:

- Those that crystallized deep within the earth's crust from liquids or by metamorphism, and which were subsequently exposed at the earth's surface by erosion.
- Rocks that formed as oceanic crust and have since been transported onto continents by plate tectonics.
- Flood basalts that cooled from giant lakes of lava.
- Volcanic rock formed by the present-day Cascade volcanos.
- Sandstones, shales, and conglomerates that formed through erosion and deposition of older rocks.
- Carbonate rocks formed from animal remains.
- Chemically deposited sedimentary rocks.

Additionally, unique physical or chemical properties of lithologies such as serpentinite, some tuffs, and carbonate rocks provide unique habitat for selected species that contributes to the landscape and species diversity of the Basin.

Different geologic processes have affected the rocks of the Basin in numerous ways during the course of geologic history. These processes (for example, erosion, deposition, consolidation, uplift, metamorphism, volcanism, and geochemical changes) have all occurred at different times throughout the history of the Basin, resulting in the different physiography, erosion characteristics, nutrient availability, and other landscape parameters present today. It is impossible, for example, to classify granite into a single erosion group or characteristic. Although much of the granitic rock of the Idaho batholith is crumbly and erodes relatively easily, other granitic units (for example, rocks in the Bighorn Crags or the Sawtooth Mountain Range) display wide ranges in natural erosion rates.

Surficial geologic units may develop directly through physical and chemical weathering of bedrock geologic units, or they may be transported from elsewhere as glacial till and alluvium, or as wind-blown dust, sand, or volcanic ash. Discussion of the surficial geologic units of the Basin and their related soil properties is presented later in this chapter.

Approach Used in Geologic Setting Description

Geologic, hydrologic, and mineral resource data were compiled, interpreted, and synthesized from published and unpublished sources and databases. The earth science themes for the Basin assessment were delineated and developed through collaboration with scientists from all SIT staff disciplines.

Individual digitized state geologic maps were used to create a lithologic group map of the Pacific Northwest, including all of Washington, Oregon, Idaho, and parts of Montana, Wyoming, Utah, Nevada, and California (map 2.2) (Johnson and Raines in press). These individual state coverages were then used to develop the derivative maps required for this study. Derivative map products included:

- Areas favorable for sand, gravel, and phosphate resources (Bookstrom and others, in press a).
- Areas favorable for cave-dwelling bats (for example, lithologies such as carbonate develop caverns, recent basalt flows contain lava tubes, and mine portals provide man-made caves) (Frost and others 1996).
- Geochemical nutrients (carbonate, potassium, iron, aluminum, magnesium, and phosphorous).
- Heavy metal distribution maps (Raines and Smith, in press).

This lithologic group map and the derivative geochemical and lithologic maps were used in developing maps for soil erosion potential and sediment supply, watershed classification, geoclimatic subsections, and potential vegetation. These maps were also used to evaluate terrestrial species habitat and "hot spots" of species richness and endemism, as well as aquatic characteristic correlation matrices and aquatic integrity indices.

Mineral resource databases of the U.S. Geological Survey (USGS) and U.S. Bureau of Mines (USBM) were queried to provide information on metallic mineral deposits and their current production status and to project possible economic development over the Basin within the next 10 years. The longer term metallic mineral resource potential of the Basin was displayed in maps of permissive or favorable rankings for the occurrence of 29 distinct mineral deposit types (Box and others, in press). The economic feasibility of development of as yet undiscovered mineral deposits in permissive areas was also described (U.S. Bureau of Mines 1995). In addition to their economic applications, such types of mineral resource information provided an assessment of likely future disturbance areas resulting from mining-related activities (Zientek and others, in press a). Mineral resource (Box and others, in press) and existing deposit information (Bookstrom and others, in press b) were used in the assessment of aquatic system integrity; past, current, and future economic activity and conditions; and biophysical environments.

Data from the National Geochemical database (Hoffman and Buttleman 1994) were used to evaluate metal loadings in streams draining areas with exposed mineral resources (Raines and Smith in press). Geochemical data from stream sediment samples were found to correlate well with geochemical characteristics delineated on the lithologic group map (Johnson and Raines, in press). Digitized versions of published hazard maps, including earthquake and volcanic hazards (Hoblitt and others 1987), as well as geothermal well and spring coverages were also produced. Stream flow, water quality, and aquifer data sets from the USGS Water Resources Division were utilized in the Economics, Broadscale Assessment of Aquatic Species and Habitats, and Landscape Dynamics assessments. Descriptions of the map themes supplied and reports generated for the project by the USGS are discussed in Chapter 8, Information System Development and Documentation.

Uses and Limitations of Geologic Information

The geologic, hydrologic, mineral resource, and process data compiled and interpreted in this assessment provide important information for addressing many issues related to ecosystem

Map 2.2—Lithologic group map of the Pacific Northwest.

pattern and process relations. The utility of geologic information in this, or any other ecosystem assessment and monitoring program, is limited only by:

- Scale of analysis.
- Completeness and appropriateness of the geologic or hydrologic database to the questions being asked.
- Understanding of the processes or patterns being investigated.

For regional-scale analysis such as the ICBEMP, generalized geologic and related derivative maps at 1:500,000 scale are appropriate for nutrient distribution description, mineral resource and mineral impact assessment, regional stream character description, and vegetation pattern analysis, among others. For watershed- or landscape-level analysis, bedrock and surficial geologic maps at scales as large as 1:24,000 or larger are commonly required to address erosion, vegetation pattern, species habitat, aquatic integrity, and other important issues.

Geologic, geochemical, geophysical, and hydrologic data have many uses in ecosystem assessment and monitoring. Earth science data (especially when combined with climatic, biologic, landscape ecology, or other data sets) provide important information for addressing many of the issues commonly identified in multi-scale ecological assessments.

Geoclimatic Settings

Hierarchical, geoclimatic-based ecological unit maps (Cleland and others, in press) were developed for regional, subregional, and landscape scale assessment efforts. Terrestrial environments described by these maps include provinces, sections (Bailey and others 1994a, McNab and Avers 1994), subsections (Nesser and others in press), and subsection groups. Provinces, sections, and subsections were used to identify progressively finer delineations of unique ecoregions with similar climate, landform, and surficial geologic material composition.

A subsection group map of the Basin (map 2.3) was constructed from individual subsection delineations (Nesser and others, in press) to display repeatable ecological units with similar climate, landforms, and surficial materials features. These mapping units were primarily used to develop watershed classifications, to map probable stream type group distributions, and to describe general hydrologic environments by ecological reporting unit (ERU). Ecoregions, subsections, and subsection groups were the primary geoclimatic maps used in most of the landscape ecology assessment work. The following discussion summarizes the construction, associated information, and general use of these various maps in the assessment process.

Ecoregions

Ecoregions represent large regional ecosystems that are uniquely identified (labeled) in geoclimatic environment mapping. Several maps and descriptions of the ecoregions of the United States have been prepared over the last several decades (Bailey 1978, 1982, 1988; Bailey and others 1994a; Driscoll and others 1984; Omernik 1987). Such maps are commonly constructed based on features such as climate, landforms, geologic materials, potential natural vegetation, land use, and soils.

In 1994, a map of the ecoregions and subregions of the United States was published at a scale of 1:7,500,000 (Bailey and others 1994a). This map delineated terrestrial biophysical environment ecological units at the following four levels of specificity: domains, divisions, provinces, and sections. Domains are normally defined using broad climatic zones. Divisions are defined using regional climatic factors. Provinces are defined using potential vegetation communities, landforms, and altitudinal zonations. Sections are further defined based on physiography (geology and topography). A companion publication (McNab and Avers 1994) to this map of the

Map 2.3—Geoclimatic subsection groups.

Nation's ecoregions and subregions was also published to provide map unit descriptions for the sections displayed on the map. Terrestrial (geoclimatic-based) biophysical environments of the Basin are displayed at the section level in map 2.4. A total of 7 provinces and 23 sections occur within the landscape ecology characterization area displayed in map 2.4.

Although some of the earlier Land System Inventories (LSI) and more recent ecoregion mapping were done at several scales, a standardized framework for their construction did not exist until recently. In 1994, a National Hierarchical Framework of Ecological Units (Cleland and others, in press) was established that defined different levels of terrestrial biophysical environment mapping appropriate to multi-scale ecological assessment efforts (table 2.1). To provide a basic overview of this mapping system, the mapping scales associated with this hierarchy are displayed in table 2.2 and the principal criteria used in map unit design are described in table 2.3.

Subsections

For the assessment of the Basin, a subsection level map of over 203 million acres was produced that identified 283 unique geoclimatic environments (Nesser and others, in press). This map was prepared at a scale of 1:500,000 because this was the only scale where associated base maps, topographic maps, and geologic maps were available for the seven states covered by the map. This map scale was also considered to be the highest resolution that could be mapped in the amount of time available that was consistent with recommendations outlined in the National Hierarchy of Ecological Units (Cleland and others, in press).

Ecosystem components considered in the delineation of subsection mapping units are the differentiating criteria used in map construction. Other components used to describe each subsection (but not in map unit delineation) are referred to as accessory characteristics. Three primary differentia (differentiating criteria) were used in constructing the subsection map for this project: geologic material, landform, and climate. These ecosystem components were considered to be the important driving variables (at the 1:500,000 scale) of many finer-scale patterns and processes within the Basin. A complete description of the differentiating criteria and accessory characteristics associated with the geoclimatic subsections of the Basin is provided by Nesser and others (in press). The following is a general summary of that information:

In development of the geoclimatic subsection map of the Basin, geologic materials were first separated by major groups of bedrock types (for example, intrusive igneous, carbonate sedimentary, and metasedimentary) and surficial materials (for example, alluvium, glacial till, and residuum). These classes of geologic materials could not be more specific than the state geology maps used in subsection map construction. Broad landform types (for example, glaciated mountains, plateaus, and plains) were the second important differentia used in map construction. General climate zones, which were inferred from general vegetation patterns, were also considered in map design (for example, grassland, shrublands, and forest). In some cases, these vegetation classes were further subdivided based on knowledge of local vegetation ecology.

Information concerning numerous other ecosystem features (accessory characteristics) was used in the description of each subsection. Examples of this information include soils, mean annual precipitation, mean annual air temperature, surface water characteristics, slope range, elevation range, and disturbance regimes. Summarization of this information was included in map unit description reports for each subsection (Nesser and others, in press).

The USGS 1:500,000 Albers Conic Equal-Area Projection Maps for the states of Montana, Idaho, Washington, Oregon, California, Nevada, Utah, and Wyoming were used as subsection base maps. Geologic materials were determined from 1:500,000 State geology maps with some minor refinements based on local knowledge. General landforms were determined using 1:500,000 State topographic maps and local knowledge.

Map 2.4—Geoclimatic sections.

Table 2.2—Typical map scales and polygon sizes of terrestrial biophysical environment ecological units.

Ecological Unit	Map Scale Range	General Polygon Size
Domain	1:30,000,000 or smaller	1,000,000s of square miles
Division	1:30,000,000 to 1:7,500,000	100,000s of square miles
Province	1:15,000,000 to 1:5,000,000	10,000s of square miles
Section	1:7,500,000 to 1:3,500,000	1,000s of square miles
Subsection	1:3,500,000 to 1:250,000	10s to low 1,000 of acres
Landtype Association	1:250,000 to 1:60,000	high 100s to 1,000s acres
Landtype	1:60,000 to 1:24,000	10s to 100s of acres
Landtype Phase	1:24,000 or larger	Less than 100 acres

Table 2.3—Principal map unit design criteria used in the construction of terrestrial biophysical environment ecological units.

Ecological Unit	Principal Map Unit Design Criteria
Domain	• Broad climatic zones or groups (such as dry, humid, and tropical).
Division	• Regional climatic types (Koppen 1931, Trewartha 1968). • Vegetational affinities (such as prairie or forest). • Soil order.
Province	• Dominant potential natural vegetation (Kuchler 1964). • Highlands or mountains with complex vertical climate-vegetation-soil zonation.
Section	• Geomorphic province, geologic age, stratigraphy, lithology. • Regional climatic data. • Phases of soil orders, suborders or great groups. • Potential natural vegetation. • Potential natural communities (PNC) (FSH 2090).
Subsection	• Geomorphic process, surficial geology, lithology. • Phases of soil orders, suborders, or great groups. • Subregional climatic data. • PNC (formation or series).
Landtype Association	• Geomorphic process, geologic formation, surficial geology, and elevation. • Phases of soil subgroups, families, or series. • Local climate. • PNC (series, subseries, plant associations).
Landtype	• Landform and topography (elevation, aspect, slope gradient and position). • Phases of soil subgroups, families, or series. • Rock type, geomorphic process. • PNC (plant associations).
Landtype Phase	• Phases of soil families or series. • Landform and slope position. • PNC (plant associations or phases).

Broad climatic zones were inferred from potential natural vegetation mapping units of Kuchler (1964) and other regional and local sources of information.

Characterization of average annual precipitation for map units was achieved using the PRISM model. PRISM (Precipitation-elevation Regressions on Independent Slopes Model) is an analytical model that distributes point measurements to a regular grid on regional to continental scales. PRISM uses a Digital Elevation Model (DEM) to estimate precipitation at each DEM cell using a regression of precipitation versus orographic elevation. Precipitation maps based on PRISM were provided by the U.S. Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS). Statewide climatic data and local knowledge were also used in subsection map development.

Soils were described for each subsection using local survey data and experience where possible. Other sources of soils information included Major Land Resource Areas and State Soil Geographic DataBases from the NRCS. DEM data and hydrography coverages were also used in the characterization of subsection map units.

Subsection maps were constructed during workshops comprised primarily of soil scientists and geologists knowledgeable about local areas. Preliminary subsection maps of parts of the Basin (Arnold 1994, Holdorf 1994) were compiled and edited by project coordinators. These maps were then reviewed and modified by soil scientists, geologists, and ecologists from the USDA Forest Service (FS), NRCS, U.S. Department of Interior (USDI) Bureau of Land Management (BLM), and USGS. A list of all the people who assisted with construction of the subsection maps for the Basin is available in Nesser and others (in press).

Brief initial descriptions of subsections were provided by Arnold (1994) and Holdorf (1994); however, most map unit descriptions were written by the same people who finalized map unit delineation. Subsection maps were redrafted, edited, digitized, and attributed by the Montana State Library and the Pacific Northwest Regional Office of the FS in Portland, Oregon. Plots of this map were constructed at 1:500,000, 1:1,500,000, and 1:2,000,000 scales for different assessment effort needs.

Subsection Groups

The 283 subsections of the Basin were combined into 39 subsection groups for subsequent terrestrial and aquatic system analysis. Groupings of subsections were made by province based primarily on similarities of landform and surficial geologic characteristics. Bedrock geology, average annual precipitation, and slope characteristics were also considered in subsection group identification. The following is a generalized description of the 39 subsection groups identified within the Basin by province (map 2.3). Only the most extensive types of rocks, landforms, geomorphic processes, and vegetation types within each subsection group are listed in these descriptions. At this level of generalization, smaller amounts of many other types of settings usually occur with a subsection group.

Great Plains-Palouse Dry Steppe Province (Number 331)

Subsection group 33101 consists of breaklands of Columbia River basalt that have been modified by stream downcutting. The general vegetative types include coniferous forest and grassland. Soils are generally coarse- to medium-textured. The subsection included in this unit is 331Af.

Subsection group 33102 consists of foothills and plateaus of basalt with a mantle of loess that have been modified by fluvial processes. The general vegetative type is grassland. Soils are generally fine-textured. The subsections included in this group are 331Aa-d and g.

Subsection group 33103 consists of plateaus of basalt with a mantle of loess that occur in areas of high precipitation and have been modified by fluvial processes. The general vegetative type is grassland. Soils are generally fine-textured. The subsection included in this unit is 331Aa.

Intermountain Semi-Desert Province (Number 342)

Subsection group 34201 consists of breaklands and steep foothills of mostly igneous extrusive rocks with lesser amounts of intrusives and sedimentary rocks. These materials have been modified by uplifting and downcutting. The general vegetative type is grassland with some coniferous forests at higher elevations. Soils are generally coarse- to medium-textured. The subsections included in this group are 342Bc and 342Ie.

Subsection group 34202 consists of plateaus and high plains of basalts and tuffs that have been modified by fluvial and aeolian processes. The general vegetative types include shrubland and grassland. Soils are generally coarse- to medium-textured. The subsections included in this group are 342Cc-e and 342Da-f.

Subsection group 34203 consists of plateaus and high plains of fluvial and lacustrine sediments and ash deposits that have been created by aeolian, fluvial, and lacustrine processes. The general vegetative types include grassland and shrubland. Soils are generally fine-textured. The subsections included in this group are 342Bd, 342Ca and b, 342Hc, and 342Ib and d.

Subsection group 34204 consists of intermontane basins and valleys composed mainly of alluvium, ash, and lacustrine materials over basalt. The general vegetative types include shrubland and grassland. Soils are generally medium- to fine-textured. Subsections included in this group are 342Bh, 342Hd, and 342Ia.

Subsection group 34205 consists of plateaus and foothills composed mainly of tuffs and basalts that have been modified by fluvial and aeolian processes. The general vegetative types include shrubland and grassland. Soils are generally coarse- to medium-textured. Subsections included in this group are 342Bb and j, 342Ch and I, 342Ha and b, and 342If and g.

Subsection group 34206 consists of mountains composed mainly of tuffs and basalts that have been modified by fluvial processes. The general vegetative types include shrubland and grassland. Soils are generally coarse- to medium-textured. The subsections included in this group are 342Ba, g, and I; and 342Cg.

Subsection group 34207 consists of foothills composed mainly of loess over basalt that have been modified by fluvial and aeolian processes. The general vegetative type is grassland. Soils are generally fine-textured. The subsection included in this unit is 342Ic.

Cascade Mixed Forest-Coniferous Forest-Alpine Meadow Province (Number M242)

Subsection group M24201 consists of glaciated mountains and foothills of igneous and sedimentary rocks that have been modified by glacial and fluvial processes. The general vegetative type is coniferous forest. Soils are generally medium- to fine-textured. The subsections included in this group are M242Ca, b, e, g, m, o-q, and s-u.

Subsection group M24202 consists of plains of ash and pumice over volcanic rocks, mostly basalt, that have been modified by alluvial and volcanic processes. The general vegetative type is coniferous forest. Soils are generally fine-textured. The subsection included in this unit is M242Cd.

Subsection group M24203 consists of mountains covered by ash or pumice and frequently underlain by igneous extrusive rocks. These materials have been modified by fluvial, mass wasting, and aeolian processes. The general vegetative type is coniferous forest. Soils are generally coarse-textured. The subsection in this group is M242Cf.

Subsection group M24204 consists of intermontane basins covered by ash, pumice, and alluvium. These materials have been modified by fluvial processes. The general vegetative type is coniferous forest. Soils are generally fine-textured. The subsection in this group is M242Cv.

Subsection group M24205 consists of mountains and foothills covered by ash and pumice and frequently underlain by igneous extrusive rocks. These materials have been modified by fluvial,

mass wasting, and aeolian processes. The general vegetative type is coniferous forest. Soils are generally fine-textured. The subsections included in this group are M242Cc and n.

Sierran Steppe-Mixed Forest-Coniferous Forest-Alpine Meadow Province (Number M261)

Subsection group M26101 consists of foothills of extrusive igneous rocks and some alluvium that have been modified by fluvial processes. The general vegetative types include shrubland and grassland with lesser amounts of forest. Soils are generally coarse- to medium-textured. Subsections included in this group are M261Da and e.

Subsection group M26102 consists of intermontane basins, foothills, and plateaus of igneous extrusive rocks overlain by ash, pumice, and alluvium that have been modified by fluvial and volcanic processes. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally coarse- to medium-textured. Subsections included in this group are M261Db and M261Ga and d.

Subsection group M26103 consists of glaciated mountains and foothills of volcanic rocks that have been modified by glacial, fluvial, and mass wasting processes. The general vegetative type is coniferous forest. Soils are generally coarse- to medium-textured. Subsections included in this group are M261Dc and d.

Subsection group M26104 consists of mountains of extrusive igneous rocks that have been modified by fluvial processes. The general vegetative type is coniferous forest. Soils are generally coarse- to medium-textured. Subsections included in this group are M261Dg and M261Gb.

Subsection group M26105 consists of mountains of extrusive igneous rocks that have been modified by fluvial processes. The general vegetative type is coniferous forest. Soils are generally fine-textured. Subsections included in this group are M261Df and h, and M261Gc.

Southern Rocky Mountain Steppe-Open Woodland-Coniferous Forest-Alpine Meadow Province (Number M331)

Subsection group M33101 consists of foothills and plateaus of volcanic and metamorphic rocks that have been modified by colluvial, fluvial, glacial, and periglacial processes. The general vegetative types include forest, grassland, and shrubland. Soils are generally medium- to fine-textured. Subsections included in this group are M331Ab, f, I, and n.

Subsection group M33102 consists of intermontane basins and valleys of valley fill, alluvium, and lacustrine materials overlying volcanic and sedimentary rocks. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally medium- to fine-textured. Subsections included in this group are M331Aa, k, and l; and M331Da, e, h, j, v, and w.

Subsection group M33103 consists of glaciated mountains of volcanic and sedimentary rocks that have been modified by colluvial, fluvial, residual glacial, and periglacial processes. The general vegetative types include coniferous forest, shrubland, and some alpine tundra. Soils are generally coarse-textured. Subsections included in this group are M331Dk, m, and t; and M331Ja-e.

Subsection group M33104 consists of glaciated mountains of volcanic and sedimentary rocks that have been modified by colluvial, fluvial, residual, and glacial processes. The general vegetative types are coniferous forest with some shrubland. Soils are generally fine-textured. Subsections included in this group are M331Dd, o, and p.

Subsection group M33105 consists of mountains of volcanic rocks that have been modified by colluvial, fluvial, and periglacial processes. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally coarse- to medium-textured. Subsections included in this group are M331Ac, d, g, h, and j.

Subsection group M33106 consists of mountains of sedimentary and volcanic rocks that have been

modified by colluvial, fluvial, residual, glacial, and periglacial processes. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally fine-textured. Subsections included in this group are M331Ae, m, o, p and M331Db, c, f, g, I, and u.

Middle Rocky Mountain Steppe-Coniferous Forest-Alpine Meadow Province (Number M332)

Subsection group M33201 consists of breaklands and foothills of granitic rocks that have been modified by fluvial, colluvial, and mass wasting processes. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally coarse- to medium-textured. Subsections included in this group are M332Aa, o, q, cc, gg, pp, and xx.

Subsection group M33202 consists of foothills of granitic and volcanic rocks with some metamorphics and sedimentary rocks that have been modified by glacial, fluvial, and residual processes. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally medium- to fine-textured. Subsections included in this group are M332Au, ll, and qq; M332Da and o; M332Fa; and M332Gb, o, r, and u.

Subsection group M33203 consists of intermontane basins and valleys of sediments that have been modified by fluvial and glacial processes. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally coarse- to medium-textured. Subsections included in this group are M332Aj, bb, ff, kk, and oo; M332Bm; M332Dk, l, and t; M332Er, u, v, w, and cc; and M332Gt.

Subsection group M33204 consists of intermontane basins and valleys of alluvium, lacustrine, and loess deposits that have been modified by fluvial, mass wasting, glacial, and aeolian processes. General vegetative types include coniferous forest, grassland, and shrubland. Soils are generally fine-textured. Subsections included in this group are M332Ad; M332Bb, e, and I; M332Eg and q; and M332Gl.

Subsection group M33205 consists of glaciated mountains of granitics and gneiss with lesser amounts of volcanic and sedimentary rocks that have been modified by glacial, periglacial, fluvial, colluvial, and mass wasting processes. General vegetative types include coniferous forest, grassland, and shrubland. Soils are generally coarse- to medium-textured. Subsections included in this group are M332Ae, f, k, m, r, t, v, ii, mm, and nn; M332Ba and d; M332De, j; M332Eb, h, x, y, and ff; M332Fi and t; and M332Gd.

Subsection group M33206 consists of glaciated mountains of granitic and sedimentary rocks that have been modified by glacial, periglacial, colluvial, and fluvial processes. General vegetative types include coniferous forest, grassland, and shrubland. Soils are generally fine-textured. Subsections included in this group are M332Ab; M332Bh; M332Ca-d; M332Ed, I, p, and z; and M332Gk.

Subsection group M33207 is heterogeneous consisting of mountains of igneous and metamorphic rocks with lesser amounts of sedimentary rocks. These materials have been modified by fluvial, colluvial, mass wasting, frost churning and glacial processes. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally coarse- to medium-textured. Subsections included in this group are M332Ah, I, l, n, s, w, x, y, z, aa, ee, hh, jj, yy, and zz; M332Bc, j, and l; M332Df and s; M332Ec, e, f, m, n, s, and aa; M332Fc, d, e, g, and h; and M332Gf, q, s, and v.

Subsection group M33208 is very heterogeneous and consists of mountains of igneous, sedimentary, and metamorphic rocks. These materials have been modified mainly by fluvial and colluvial processes with lesser amounts of glaciation, frost churning, and mass wasting. The general vegetative types include coniferous forest, grassland, and shrubland. Soils are generally fine-textured. Subsections included in this group are M332Ag; M332Bf, g, k, and n; M332Db-d, g-I, m, n, q, and r; M332Ea, k, l, t, and dd; M332Fb; and M332Ga, and g-j.

Subsection group M33209 consists of plateaus of basalt and granite that have been modified by fluvial and colluvial processes. The general vegetative types include forest and grassland. Soils are generally medium- to fine-textured. Subsections included in this group are M332Ap, and rr; and M332Gm, n, and p.

Northern Rocky Mountain Forest-Steppe-Coniferous Forest-Alpine Meadow Province (Number M333)

Subsection group M33301 consists of foothills of granitics and gneisses that have been modified by fluvial and colluvial processes. The general vegetative types include coniferous forest and grassland. Soils are generally fine-textured. Subsections included in this group are M333Am and M333De.

Subsection group M33302 consists of intermontane basins, valleys, and till plains of lacustrine, glacial outwash, alluvium, and till. The general vegetative types include forest and grassland with a smaller amount of shrubland. Soils are generally medium- to fine-textured. Subsections included in this group are M333Ac, d, r, and s; and M333Bc.

Subsection group M33303 consists of glaciated mountains of granitic and metasedimentary rocks that have been modified by glacial and fluvial processes. The general vegetative type is coniferous forest. Soils are generally medium- to fine-textured. Subsections included in this group are M333Aa, b, e, and h-k; M333Ba, b, and e; and M333Ca, b, d, and g.

Subsection group M33304 consists of mountains and breaklands of granitic and metasedimentary rocks. These materials have been modified mainly by fluvial and colluvial processes with some frost churning and alpine glaciation at higher elevations. The general vegetative type is coniferous forest. Soils are generally medium- to fine-textured. Subsections included in this group are M333Af, g, o, and q; M333Bf; and M333Da-d, and f-j.

Potential Vegetation Settings

This section summarizes the approach used to model the distribution of broad-scale potential vegetation (PV) settings over the assessment area. Although the specific definitions may change, PV is always understood to be an expression of the biophysical environment of an area regardless of the study scale or existing vegetation status (Eilenberg 1988, Kuchler 1988). The methods used in PV classification and mapping, as well as descriptions of the PV environments identified within the Basin, are outlined in Reid and others (1996). The following is a summary of that report.

Potential vegetation maps are used in conjunction with other maps of abiotic features, such as landforms, to define biophysical environments at different spatial scales (Zonneveld 1989). Such maps provide the context for understanding relations between disturbance regimes and other ecological processes and the existing landscape patterns of an area, such as the existing vegetation. Potential vegetation maps are also commonly used as input into models of landscape pattern change under various scenarios such as different management strategies or global climate change. In this assessment, PV maps were used for different portions of the Terrestrial, Aquatic, and Landscape Ecology staff assessments see Chapters 5, 4, and 3 respectively. For example, PV maps were used as input to the Columbia River Basin SUccession Model (CRBSUM) for modeling change in vegetation patterns under a doubling of carbon dioxide (CO_2) scenario. PV maps were also used in the construction of hydrologic subregion maps.

Methods Used in Broad-Scale Potential Vegetation Classification and Mapping

The dependent variable of the vegetation site model used in broad-scale PV mapping was a vegetation type. Over large areas such as the Basin, there was a need to use a standardized and regionalized classification system (Bourgeron 1988 and 1989). In this modeling exercise, The Nature Conservancy's (TNC) Western Regional Vegetation Classification (WRVC) (Bourgeron and Engelking 1994) was

adopted. This classification included the existing natural and semi-natural vegetation in the western United States. (See Reid and others 1996 for further discussion of the WRVC and its development and use).

Potential vegetation classifications were generated at three classification scales: section, regional, and coarse. Initial classifications were developed by dividing vegetation types into three broad physiognomic classes: forest, shrubland, and herbaceous types. Potential vegetation types and their relationship to temperature-moisture gradients were then defined for each physiognomic class: (1) for each geoclimatic section (section level) and (2) across the entire assessment area (regional level). A coarse-level PV classification was generated by defining 20 PV types in relation to Basin-wide temperature-moisture gradients, regardless of the physiognomic type.

The process of determining the potential vegetation classifications and their temperature-moisture gradient relations included the generation of a list of PV plant associations over the Basin and the arrangement of the potential plant associations into section-level classifications.

The general approach used was to consider as PV all plant associations that represented the end point of successional sequences. A master list of such plant associations by physiognomic class was generated from the WRVC for the Basin (Reid and others 1996). This master list was revised as necessary before, during, and after all the workshops used in PV map construction. A total of 807 plant associations were associated with the classifications used in PV mapping (Reid and others 1996).

Section-level PV classifications were built for each of the three broad physiognomic classes of vegetation (forest, shrubland, and herbaceous types) from the master list of PV plant associations. This task was accomplished in various workshops by staff from the FS, U.S. Fish and Wildlife Service (USFWS), BLM, NRCS, and TNC, as well as other professionals with broad regional knowledge of these PV plant associations.

Moisture and temperature gradients were divided into four coarse segments resulting in 4 by 4 matrices (four temperature settings by four moisture settings). Workshop participants were asked to list the PV plant associations within each temperature-moisture setting (for example, cold or wet setting) for each physiognomic class. There were 16 PV types for each physiognomic class, for a total of 64 possible PV classes within each geoclimatic section of the Basin. An example of this classification system is provided in table 2.4.

Temperature and moisture gradients were scaled by physiognomic class within each geoclimatic section. For example, within a given section, the cold or wet cell for forests was not necessarily equivalent to the cold or wet cell for the shrublands. Moreover, a given temperature-moisture cell [for example, cold (or wet) for forests] was not necessarily equivalent among geoclimatic sections (for example, between a high mountain section and a low desert section).

Section-level classifications were aggregated into a regional classification using regional temperature-moisture 4 by 4 matrices for each physiognomic class. This process created three regional PV classifications, one for each physiognomic class for a total of 48 regional PV types (Reid and others 1996). A coarse-level temperature-moisture matrix of 20 cells was also created. In constructing this matrix, the 48 regional PV types were aggregated into the cells of the coarse-level matrix regardless of their physiognomic class. Descriptions of the vegetation types in both the regional and coarse-level PV classes are provided by Reid and others (1996).

The independent variables (related to the vegetation type dependent variable described above) for the vegetation model were selected on the basis of their ability to be derived from the DEM data for each 1-km^2 pixel of the grid covering the entire Basin. Elevation, slope, and aspect (table 2.5) were chosen since they are closely related to the direct ecological factors that define potential vegetation environments (for example, solar radiation). The assignment of the biophysical settings to section-level PV classes (model calibration) was done on a geoclimatic subsection basis by professionals with local field experience (Reid and others 1996).

Table 2.4—Forest biome temperature-moisture gradient potential vegetation classifications for section M333C of the Basin (Reid and others 1996).

Table 2.5—List of site parameter/GIS rules used in the "vegetation-site" model for broad-scale potential vegetation environment mapping.

Elevation (meters)	Aspect	Slope
0 -304	Northeast	Flat
305 -609	Southwest	5 - 29%
610 -914	Flat	30 - 59%
915 -1,219		Greater than 60%
1,220 -1,523		
1,524 -1,828		
1,829 -2,133		
2,134 -2,438		
2,439 -2,743		
2,744 -3,047		
3,048 -3,352		
3,353 -3,657		
3,658 -3,962		
3,963 -4,267		

Section-level PV mapping was accomplished within each geoclimatic subsection by reading the slope, aspect, and elevation values for each pixel and using them to index the name of the section-level PV type in the pixel. Inaccuracy in the DEM was corrected during a series of workshop sessions conducted for quality control of the three scales of maps produced.

Predictive models of coarse-level PV type distributions were constructed based on current and projected future climate data. The coarse-level PV map generated for the Basin (map 2.5) was used to provide the source of PV data under current climatic conditions. The resulting models were used to produce maps of predicted PV environments under current climate conditions and a doubled CO_2 climate change scenario.

Generalized linear models were used to quantify PV response to climatic conditions in this study. Nine climate attributes were selected as predictor variables in the analysis. A map of the distribution of 20 PV types under current climatic conditions previously generated for the assessment (Reid and others 1996) provided the source of PV data used. To construct the models, the current climatic conditions generated over the Basin at a 2-by-2-kilometer scale for a normal climate year (Thornton and Running 1996) were associated with the pixels of the base PV map. For a more complete description of the modeling approach and climatic attributes used in this characterization refer to Thornton and others (in press).

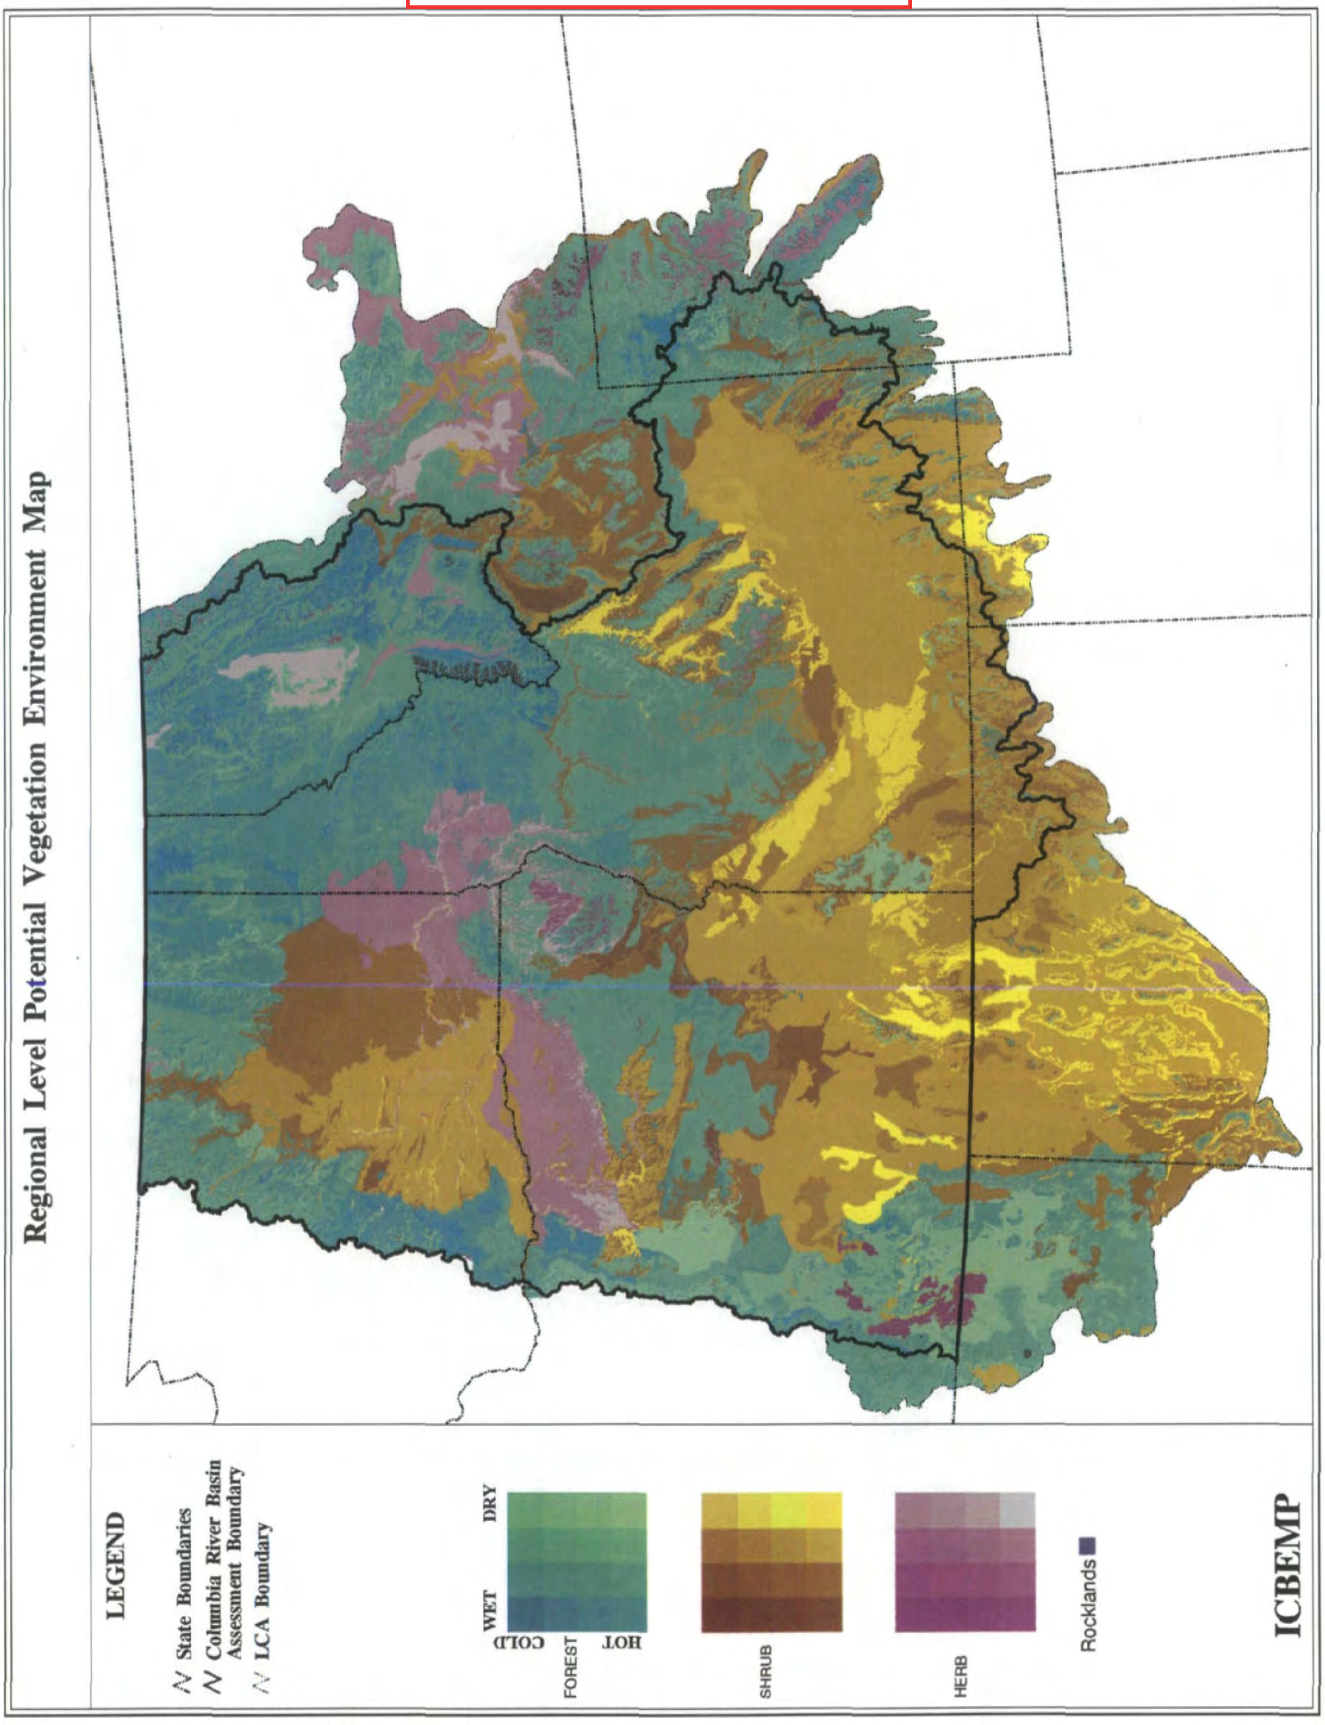
Riparian Potential Vegetation Settings

Riparian plant associations within the Basin were identified based on the Regional Hierarchical Classification of Western United States Vegetation (Bourgeron and Engelking 1994) and a series of workshops involving local experts. These plant associations were then aggregated into Riparian Plant Association Groups based on climatic zone, vegetation structure, and moisture status/indicator species criteria. Riparian Plant Association Group composition was assigned by workshop participants to dominant valley bottom settings within each of the 48 regional-level PV environments described above. This assignment facilitated spatial identification of probable riparian PV environments at a 1-km^2 grid throughout the Basin. Descriptions and methods used in the classification and mapping of riparian plant association groups are provided by Manning and others (in press).

Results of Broad-Scale Potential Vegetation Classification and Mapping

A map was produced for each geoclimatic section using the section-level PV classifications and their assigned elevation, aspect, and slope settings by subsections (Reid and others 1996). These maps were reviewed by TNC, and State Heritage ecologists, as well as FS and BLM professionals. Overlapping and missing data areas in these maps were corrected, and changes in vegetation-site classifications were made as necessary and subjected to further review.

Calibration of vegetation-site models was performed separately for each PV type by elevation class within each geoclimatic subsection. Once vegetation-site models were revised, resulting attribute matrices were generated section by section to describe the possible ecological range of each section-level PV class. Table 2.6 provides an example of an attribute matrix for the Northern Rockies section (see Reid and others 1996 for a description of all sections). A final map of all section-level potential vegetation environments was produced at a 1:2,000,000 scale (Reid and others 1996).



Coarse- and regional-level potential vegetation environment maps (maps 2.5 and 2.6) were produced from section-level maps by establishing relations between section-level classes and regional classes and then establishing relations between regional classes and coarse-level classes (Reid and others 1996). All maps produced by this process were reviewed, and as with the section-level PV map, overlapping and missing data areas and obvious errors in the maps were corrected.

Broad-scale potential vegetation environment maps were analyzed to inspect general patterns between vegetation and elevation at different spatial scales. Area statistics for these maps [in square kilometers (km^2)] were provided by Reid and others (1996) for frequency and relative percentage of:

- Main elevational classes by geoclimatic section.
- Section-level PV classes by geoclimatic section.
- Regional-level PV classes across the Basin.
- Coarse-level PV classes across the Basin.

To evaluate the performance of vegetation site model and the quality of the model-generated potential vegetation maps, quantitative comparisons were made between the model-generated maps and field data collected on plots within the Northern Rockies section. This section was chosen as a test area because of the large number of previously sampled plots and the known level of confidence in the PV assignments by field investigators. The three main limitations to the use of plots for map evaluation discussed in Reid and others (1996). A total of 2,545 plots with reliable PV plant association assignment were used in this evaluation.

Map performance was based on the percentage of plots in which the predicted map class and the observed class were identical. On the average, correspondence between predicted PV and plot data for all PV types was 29 percent at the section level, 32 percent at the regional level, and 31 percent at the coarse level (Reid and others 1996). The comparisons were broadened to include the chance of making an error of one class (Reid and others 1996). For forest classes, the degree of correspondence was on the average 45 percent at the section level, 46 percent at the regional level, and 43 percent at the coarse level (Reid and others

1996). These numbers were encouraging because, as a consequence of the limitations discussed by Reid and others (1996), the quantified degree of correspondence between the maps and the plot database were expected to be much lower than between model-generated maps and current methods of accuracy assessment.

The models used to predict potential vegetation environments were correct (on average) close to half of the time when an error of one class was allowed. These results are similar to those described by other scientists in Switzerland (Brzeziecki and others 1993) and in California (Walker and others 1995). Such models are interesting because they could be modified easily to conform to new information, and they could be used to identify relations between vegetation and driving (direct) variables through the use of simple process models.

Predicted changes in PV distribution under a double CO_2 scenario were also assessed in this study by comparing predicted future PV with predicted current PV maps. Examination of these maps allowed identification of areas in which change is predicted to occur in a particular direction, as well as areas in which little change might be expected. Results of this analysis indicated that, in general, following climate change of the type projected, mesic vegetation types are predicted to expand in area across the Basin.

Climate attributes were entered into a model for each PV class using a forward step-wise procedure in the analysis of PV distribution change. The equation resulting from model development for each PV class was used to predict probability of occurrence ranging from 0 to 1. Individual model performance evaluation was then conducted on validation data sets. Accuracy was 65 to 87 percent of pixels correctly predicted. The 20 equations developed in this study were then used to predict the PV class for each pixel over the entire Basin under both current climatic conditions and predicted climatic conditions under a scenario of doubled CO_2. To generate maps of PV climate change, the highest probability of occurrence of a PV class for each pixel was selected.

Extensive overlap in climate attribute values occurred among PV classes. In addition, the base PV map used as a data source in analysis had a different spatial scale (1- by-1 km) than the climate attributes (2-by-2 km). Consequently, when comparing the model-predicted current conditions PV map with the base PV map, only 35 percent of pixels were correctly predicted. When the three highest probabilities of occurrence were used to determine whether the correct PV class was predicted, accuracy was 72 percent.

Drainage Basin Settings

Delineation

Continuous delineations of watersheds across the assessment area were developed to facilitate integration of terrestrial and aquatic ecosystem information. The procedures used in watershed delineation were described in detail by Brewer and Callahan (in press). A total of approximately 7,500 base unit subwatersheds (6th-field HUCs) were identified within the Basin, and about 12,000 subwatersheds were identified within the landscape characterization area. Delineation of these hydrologic units was consistent with national direction and existing interagency efforts within and near the assessment area. Watersheds by their very nature are a nested hierarchy; a small watershed is contained within a larger watershed which, in turn, is contained within a still larger one. The delineation and numeric identification of watersheds used in the assessment of the Basin follows a similar logic. The numeric coding system used was based on the one prepared by the USGS in cooperation with the Water Resources Council. This system consists of fields of paired digits referred to as Hydrologic Unit Codes (HUC). The first four fields (8 digits) are assigned and published by the USGS and are commonly referred to as 4th-field HUCs. The ICBEMP watershed delineation further subdivides 4th-field hydrologic units into smaller, nested

5th-field and 6th-field hydrologic units. It is the 6th-field hydrologic unit (referred to as 6th-field HUC or subwatershed) that was used as the basic characterization unit for the ICBEMP assessment effort.

Subsampling

Land and hydrologic unit sampling framework—To provide insight into management induced cause-and-effect relations between terrestrial and aquatic ecosystems, it is preferable that ecological characterizations classify environments as terrestrial (biological and physical) and hydrologic at scales appropriate to observing the patterns, processes, and interactions of interest. For example, if an analysis is to evaluate effects of roads on the distribution of bull trout life histories in an area, the analysis area ought to consist of hydrologic units that are large enough to represent a nearly full complement of trout life histories. If this was not the case, it would be difficult to separate effects of stream network size from the effects of hydrology, climate, geology, vegetation, and landform. The ECOMAP hierarchy (Cleland and others, in press) provided the framework used in the identification of terrestrial ecological units in this assessment, and the USGS hydrologic unit hierarchy (Seaber and others 1987) provided an initial framework for hydrologic unit identification. Both terrestrial and hydrologic criteria were used to stratify watersheds for sampling and characterization in this assessment.

The USGS hydrologic unit hierarchy provides a nested four-level delineation of watersheds of similar size and scale for the entire United States. The fourth level in this hierarchy (4th-field HUCs) was used to initially stratify watersheds of the assessment area for sampling. In addition, results from the Eastside Forest Ecosystem Health Assessment (Lehmkuhl and others 1994) indicated that smaller hydrologic units of 8,000 or more hectares (20,000 acres) were suitable for characterizing (on a sampling basis) patterns and trends in structural attributes (both composition and configuration) of vegetation within 4th-field HUCs. Complete hydrologic unit coverages of this scale for the entire Basin were lacking in the existing USGS hierarchy. Consequently, two additional nested levels (5th- and 6th-field HUCs) were delineated for this assessment.

Subbasin and Subwatershed Selection

Subbasins were selected from a formal stratification of all subbasins by their province-level ecological unit membership and similarity of area in 305 meter (1,000 ft.) elevation zones. Subbasin areas in each elevation zone were derived in a geographical information system (GIS) using a 90-meter DEM at a scale of 1 kilometer with raster coverages. Similarity analyses employed the percent similarity algorithm (Pielou 1984) shown below:

$$ps=200\ \frac{\sum \min (x_i y_i)}{\sum x_i+\sum y_i}$$

where:

x_i = is the measure of attribute i in subbasin x,
y_i = is the measure of attribute i in subbasin y,

Generated pixel data were treated like any ecological data set consisting of sample units (subbasins) with species abundances (pixel counts within each province-elevation class). The intent of this analysis was to classify groups of similar subbasins. A smaller set of subbasins was then randomly drawn from within each group, from which subwatersheds were then randomly selected. Each group contained similar subbasins where the attributes of similarity were the province-elevation classes. Since provinces are by definition relatively homogeneous ecological land units at that scale (Cleland and others, in press), this approach was considered to be a reasonable method of stratification. A recursive analysis was used in the identification of subsample watersheds.

The following is a brief description of the steps used in each analysis cycle of that process:

1. The cluster analysis procedure TWINSPAN (TWo-way INdicator SPecies ANalysis) was used to divide the data into 4 to 6 groups (Hill 1979).
2. Two similarity index tables were developed using the percent similarity index (Pielou 1984). The first table was a subbasin comparison. Percent similarity uses abundance data to weight the importance of each attribute. For example, two subbasins with similar attributes that have similar abundance values would have higher values than two subbasins also having similar attributes but divergent abundance values. The second table was a cluster by cluster comparison using TWINSPAN output. These values represented averages of all the within-group or between group similarity values from the first table. Assessment of cluster homogeneity with respect to the presence or absence of attributes was possible using this table.
3. The similarity analysis described above was used and the membership of each cluster refined. The process for each cluster defined above was repeated, applying steps 1 and 3 for each cluster, and stopping when further division produced clusters too small to be useful or when further subdivision was not ecologically meaningful.

Sixteen subbasin strata were identified by this stratification process. These strata contained 4 to 18 subbasins, of which 2 to 4 were randomly selected without replacement from each stratum for sampling. The sampling intensity used in the Eastside Forest Ecosystem Health Assessment (Everett and others, 1994) across each stratum was in proportion to stratum size. Subbasins previously selected for the Eastside Forest Ecosystem Health Assessment (Everett and others 1994, Lehmkuhl and others 1994) were included in the sample because these data were readily available, and subwatersheds within these subbasins were randomly selected. In all, 43 subbasins were sampled for vegetation and stream pattern changes with current and historic aerial photos (map 2.7).

Subwatersheds were randomly selected for vegetation mapping until at least 15 percent of the area of each selected subbasin was represented. Availability of recent historical and current aerial photography was researched for each selected subwatershed. Aerial photo coverages of selected subwatersheds were unavailable or incomplete for a few subbasins containing mostly private lands or rangelands. These subbasins were randomly replaced with others having sufficient photo coverage as they were encountered in the selection process. Ultimately, 337 subwatersheds were selected for sampling of aerial photo vegetation and stream patterns (map 2.7).

A primary concern in using subwatersheds of different sizes in vegetation pattern analyses is the correlation between landscape pattern attributes and landscape area (O'Neill and others 1988, Turner 1989). Recent studies have shown that sample estimates of landscape attributes change asymptotically rather than linearly with landscape area (Lehmkuhl and Raphael 1993). Accordingly, subwatersheds averaging at least 4,000 hectares (10,000 acres) in size were selected for sampling to avoid bias associated with smaller sampling units. When subwatersheds smaller than 4,000 hectares were encountered in the sample, they were joined with an adjacent subwatershed to make larger hydrologic units for sampling.

Classification

Hydrologic regions and subregions were identified within the Basin through grouping of similar 4th- and 6th-field HUCs (respectively) based on geoclimatic, morphometric, and hydrologic function criteria. Primary objectives for development of these watershed classification groupings included:

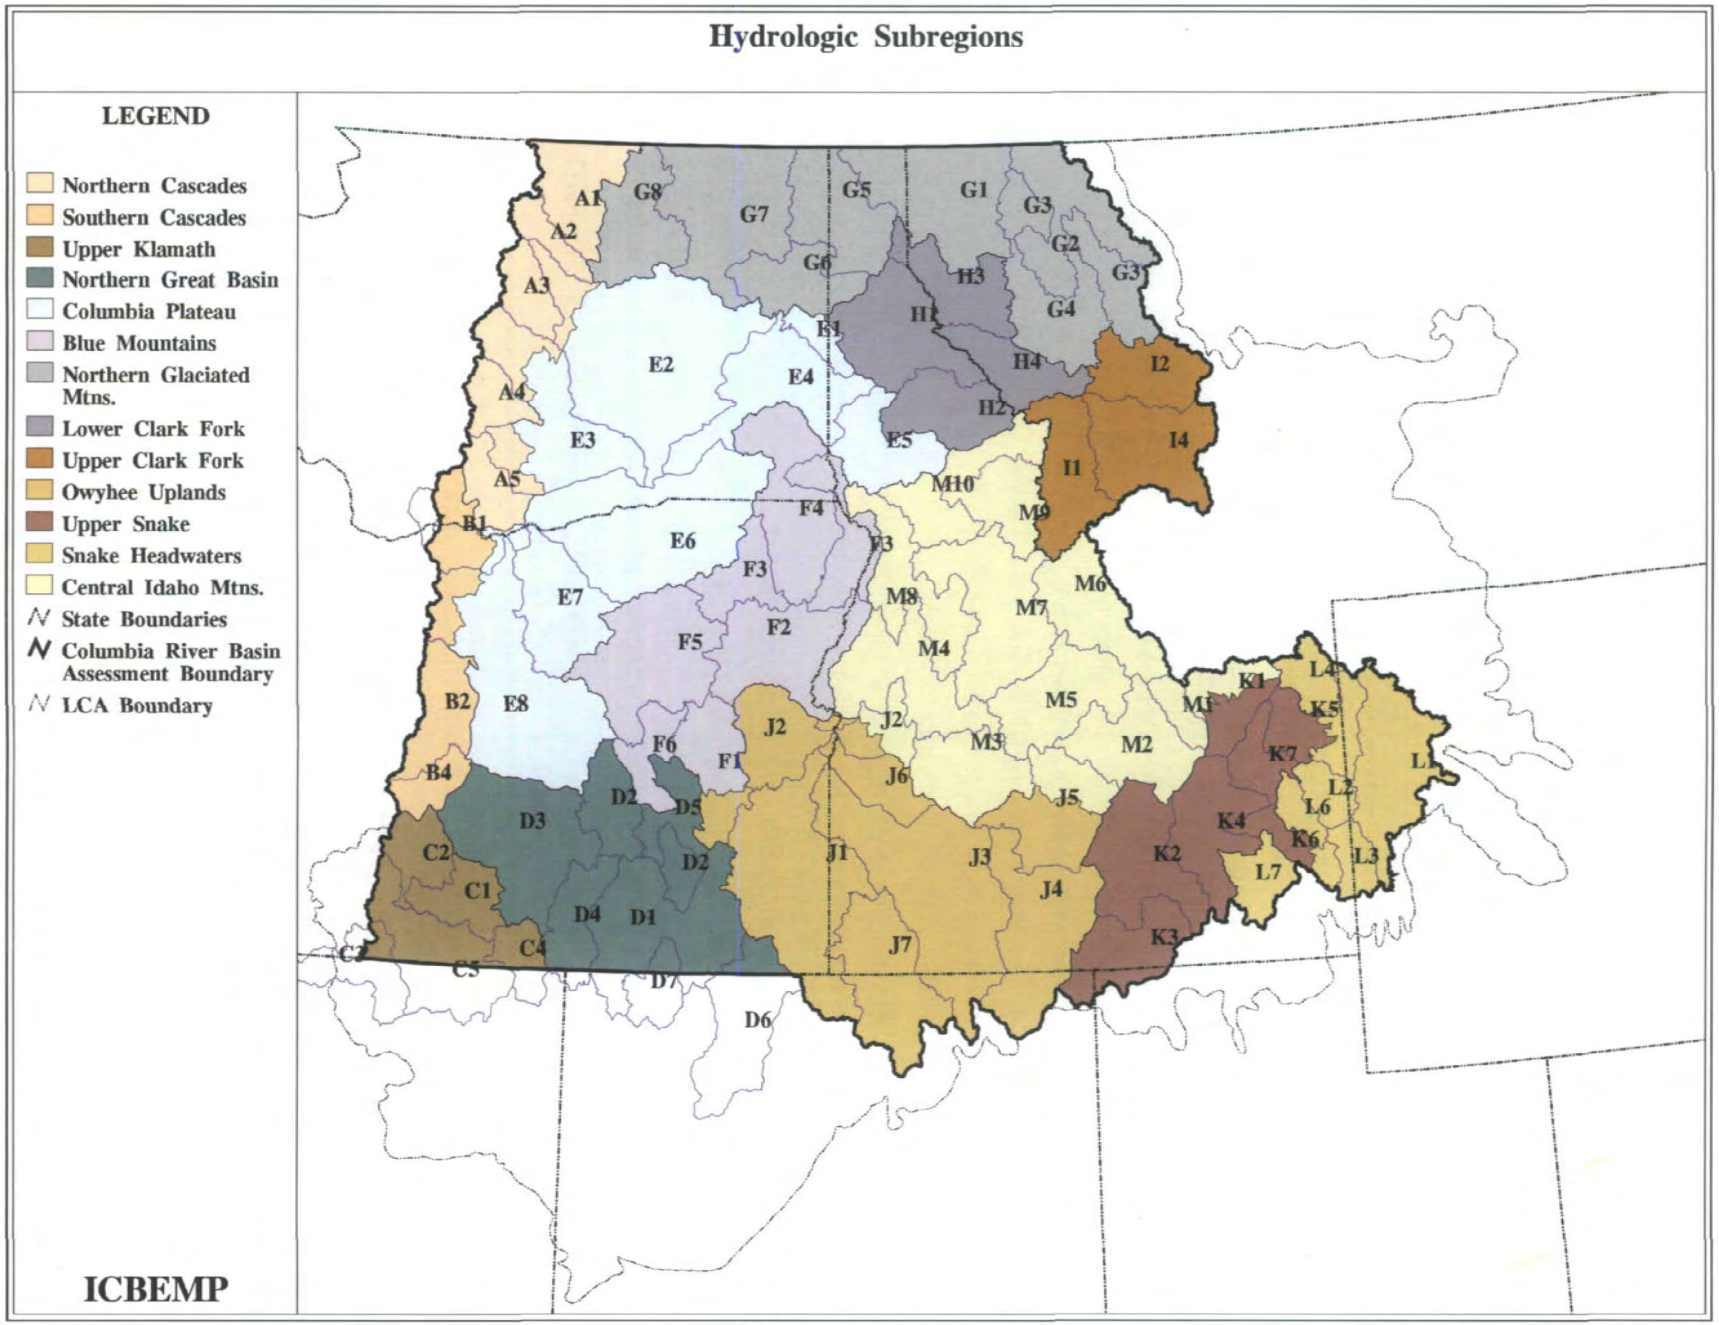
- Prediction of finer-scale aquatic patterns (for example, valley bottoms, stream types, and channel units).
- Identification of watershed settings with similar management potentials and response to disturbance.

Map 2.7—The subbasins and subwatersheds used in vegetation and stream pattern trend subsampling.

Methods and results of the watershed classification procedures used in this assessment are described in Jensen and others (in press). The following is a brief summarization of information contained in that report.

A draft map of hydrologic regions within the Basin was constructed for this project based on the composition of geoclimatic subsection groups and regional scale potential vegetation environments within each 4th-field HUC. These composition values were used in an agglomerative hierarchical clustering analysis (Ward 1963), which indicated that 14 groupings of 4th-field HUCs provided optimum classification of the subbasins within the Basin based on the biophysical environment variables studied.

Classification groupings identified through cluster analysis were associated to a data file for each 4th-field HUC (see Appendix 2A), which was used to produce an initial map of 14 hydrologic subregions within the Basin. This map was subsequently refined (in conjunction with other materials) in the development of an ecological reporting unit (ERU) map that identified 13 environments (hydrologic regions) across the Basin. ERUs were developed in this project to facilitate common reporting of analysis information between different staffs. Hydrologic information is summarized by ERUs later in this chapter.



A subwatershed-based (6th-field HUC) map of 84 hydrologic subregions within the Basin (map 2.8) was developed following hierarchical principles of ecological unit mapping as described by the ECOMAP working group of the FS (Cleland and others, in press). The primary objective for identification of hydrologic subregions (at a 1:500,000 scale) was to predict areas with similar finer scale aquatic pattern composition (that is, valley bottoms and stream types), and hence similar management potential and response to disturbance (Jensen and others 1996). Realization of this objective required:

- Aerial photo estimation of valley bottom and stream type composition within subsample watersheds.
- Identification of direct and indirect biophysical environment variables that were the best predictors of valley bottom and stream type compositions within subsampled watersheds (tables 2.7, 2.8a and 2.8b).
- Development of hydrologic subregion maps based on the primary biophysical environment variables identified.

Canonical correspondence analyses indicated that a core set of 15 direct variables (for example, average watershed slope, drainage density, and 10-year peak flow) and 19 indirect variables (that is,

Table 2.7—Listing of the direct and indirect biophysical environment variables used in the subregional scale watershed classification of the Basin.

Table 2.8a—Description of the primary direct biophysical environment variables considered in subregional-scale watershed classification of the Basin. (Note: All variables were calculated to reflect average values for a 6th-field subwatershed.)

Variable Code	Description
Slope	Percent slope, calculated from a 90-meter digital elevation model.
DDensity	Drainage density (total stream length/watershed area).
MINZ	Minimum elevation (m).
MAXZ	Maximum elevation.
Relief	Relief ratio (MAXZ-MINZ/Watershed Area).
STE	Sediment transport efficiency (D Density x Slope).
Flood10	Estimated pore point, 10-year peak flow level [cubic feet per second (cfs)].
24-hour	2-year maximum 24-hour storm intensity (cm).
PRECIP	20-year average annual precipitation (cm).
SUPRCP	Average daily precipitation for summer months (June, July, August).
JULYTAVG	Average daily air temperature (Celsius) for July.
AUGTAVG	Average daily air temperature for August.
WNTMAX	Average daily maximum air temperature for winter months.
WNSRAD	Average daily solar radiation loading (Langleys) for winter months (December, January, February).
TDEW	Average annual daily dew point temperature.

9 subsection groups, 4 lithology groups, and 6 regional potential vegetation settings) accounted for approximately 30 percent of the species-sample and 76 percent of the species-environment variability that existed within the 337 subwatersheds sampled in this assessment (tables 2.8a and 2.8b). The 19 indirect biophysical environment variables identified in this analysis were used to produce an ecological unit classification of 7,462 6th-field subwatersheds within the Basin by a hierarchical agglomerative clustering technique (that is, hydrologic subregions were identified).

Discriminant analysis indicated that 13 direct biophysical environment variables could correctly assign 80 percent of the 6th-field subwatersheds to their indirect biophysical environment classification, thus demonstrating the strong relation that exists between indirect biophysical environment classifications (ecological units) and the direct biophysical environment variables that determine finer-scale aquatic patterns. This relation was further supported by the fact that hierarchical clustering of 6th-field subwatersheds by 13 direct biophysical variables produced exactly the same results as those obtained with 19 indirect biophysical variables. Analysis of variance indicated that subregional watershed classifications were also effective in explaining observed differences in stream type groups and management hazard ratings across all 6th-field subwatersheds. Results of this analysis indicated that ecological units (that is, indirect biophysical environments) could be effectively used to produce watershed classifications that integrate the effects of direct biophysical variables on finer-scale aquatic patterns and their associated opportunities and limitations for management. Map unit descriptions of the hydrologic subregions identified in this analysis will be provided in future publications.

Table 2.8b—Description of the primary indirect biophysical environment variables considered in subregional watershed classification of the Basin. (Composition of these variables within each 6th-code subwatershed was calculated for analysis.)

Biophysical Group	Variable Code	Description
Lithology Groupings	Litho-5	Calcareous meta-volcanics.
	Litho-8	Conglomerates.
	Litho-17	Lake sediments and playas.
	Litho-19	Loess.
	Litho-23	Mafic pyroclastics.
	Litho-25	Mafic volcanic flows.
	Litho-26	Metamorphosed conglomerates.
	Litho-32	Mixed eugeosynclinal materials.
	Litho-36	Sandstone.
	Litho-40	Ultramafic materials.

Stream Type Settings

The morphology of a natural stream channel is a function of current climate and the landform, lithology, and vegetation through which the stream flows. These biophysical patterns determine the streamflow regime, types of valley fill materials, channel substrate, and slopes of valley bottoms and stream channels. The morphology of a stream reach, in turn, determines the type and distribution of finer-scale, in-channel, habitat features such as pools, riffles, and glides; the interaction of the channel with its bed and floodplain; the dissipation of flood energy; and the ability of a stream to transport its sediment load.

Several methods exist for classifying stream channels. Many of these classification methods share similar parameters such as: valley width, valley slope, channel slope, channel planform, channel width and depth, and substrate materials (Maxwell and others 1995, Montgomery and Buffington 1993, Rosgen 1994). In this analysis, Rosgen stream types (Rosgen 1985, 1994) were used to classify streams interpreted from current and historic aerial photo coverage of subsampled watersheds and to estimate the distribution of grouped stream types across the Basin. The Rosgen stream type classification method was used because of its practicality (Minshall 1994) and its prior extensive use by BLM and FS personnel. This classification system also provides interpretations for stream types that are very useful in watershed analysis (Rosgen 1994).

The Rosgen stream type classification system is hierarchical. For example, level I of this system primarily uses stream planform pattern, stream longitudinal profile, and valley and landform characteristics that can be derived from aerial photography and topographic maps to classify streams as A, B, C, D, E, F, G, or DA types (Rosgen 1994). The morphology of level I stream types is illustrated in figure 2.3. Level II of this classification system requires additional field knowledge of parameters such as stream substrate size, bankfull width and depth, and entrenchment ratios. These additional parameters permit more refined interpretations of stream channel stability, sediment regime, and recovery potential. Channel substrate material is a particularly important parameter, and can generally be inferred from soils and geologic maps (Rosgen 1994) or customized watershed classifications (Jensen and others in press).

In this analysis, stream types were defined using modifications of Rosgen's (1994) classification methods. Three modifications were used to accommodate different data sources and types of analyses:

- Stream types A, B, and C: Channel habitat data from fisheries inventories across the Basin were aggregated into these three stream types, using valley slope and valley width criteria. Available fisheries inventory did not permit refinement of the Rosgen (1994) classification to reflect stream braiding or entrenchment of the channel within its valley (that is, stream types D, DA, E, F and G could not be identified). Preliminary tests of channel unit data indicated fair to good agreement between classified A, B, and C types and field estimates of similar stream types made by FS biologists. These A, B, and C stream types corresponded roughly to the source, transport, and response reach designations as defined by Montgomery and Buffington (1993). In terms of slope and valley criteria, source reaches would be classified as an A stream type; transport reaches would be classified as B, G, and D stream types; and response reaches would be classified as C, E, DA, and F stream types. Relative to these source, transport, and response designations, the level I Rosgen classification system provided more interpretations for management. For example, although B, G, and D stream types can all exist on a 2 to 4 percent slope, they respond very differently to changes in streamflows and sediment loads.
- Level I stream types A through G: Synoptic aerial photo coverage (1:20,000 to 1:12,000 scale) of 357 subsampled 6th-field subwatersheds were interpreted to estimate the distribution of stream types within each subwatershed. In

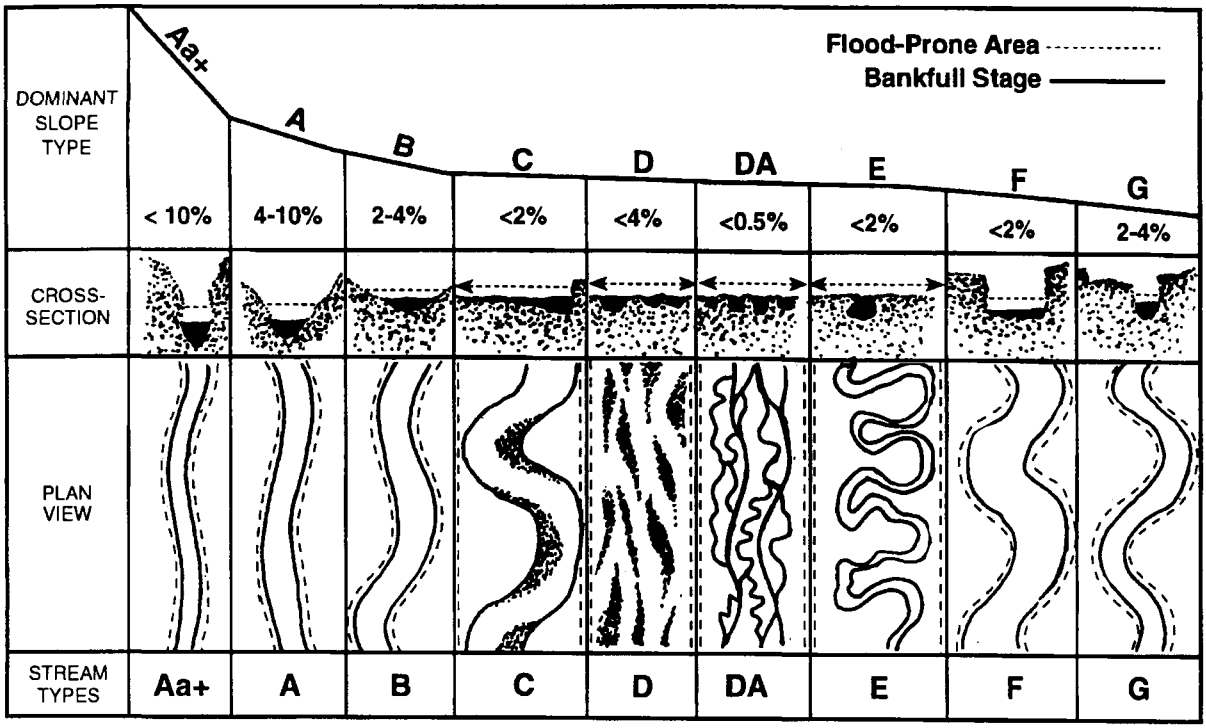

Figure 2.3—Longitudinal, cross-sectional, and plan views of major stream types (after Rosgen 1994).

addition, these photo interpretations recorded the presence of channelized streams, wetlands, beaver dams, and lakes (Brewer and others, in press b). Photo-interpretation results were checked for errors in application of classification rules (for example, the identification of an E stream type which was defined as a very low-gradient, highly sinuous channel on valley slopes of greater than 10 percent, and vice versa) throughout the photo-interpretation process. The photo-interpreted stream types characterized in this effort have not been field verified. Data from this sampling effort were used primarily in the development of sub-regional scale watershed classifications.

- Stream type groups 0-17: Level II of Rosgen's (1994) stream classification identified 42 stream types [that is, 8 alpha-types of Aa through G; and 6 subdivisions denoted numerically (1-6) that describe dominant channel materials, varying from bedrock to silt]. For this analysis, these 42 stream types were aggregated into 18 groups, based on similarities in morphology and channel materials, and hence, similarities in sensitivity to changes in streamflow and sediment. Table 2.9 outlines the relations among stream type groups, individual stream types, characteristic landform and geology, bedforms, energy and gradient characteristics, characteristic mode of stream adjustment, and in-channel and riparian habitat characteristics.

The probable distribution of stream type groups was estimated continuously across the Basin through various subject matter expert workshops and subsequent GIS modeling. The GIS map

Table 2.9—Description of the stream type groups used in the hydrologic characterization of the Basin.

Stream Type Group Code	Individual Stream Types	Characteristic Landform, Geology	Bedform	Energy/Sediment Characteristics	Characteristic Mode of Adjustment	In-channel and Riparian Habitat Characteristics
00	A1, A2	Structurally controlled, such as faults and bedding planes; talus, glacial moraines, lag deposits.	Step/pool & cascades; pools irregularly spaced at about 2-3 widths.	High energy, dissipated by frictional resistance from bedrock and boulders. Low sediment supply; low bedload; low sediment storage.	Morphology minimally affected by changes in flow or sediment, but LWD important to increase pools and sediment storage.	Steep (e.g., 10% + can act as barriers to fish migration. Discharges up to approx. 50 yr. R.I. inundate only narrow zone adjacent to stream.
01	A3	Glacial moraines & tills; alluvial fans; lag deposits; slide debris; tributaries incised in terraces.	Step/pool & cascades.	High energy, dissipated against bed and banks. High sediment supply; high bedload supply and transport.	Stores large volume of sediment in pools and behind LWD. Episodic inputs of sediment. Steep forms (>10%) associated *with debris avalanches and mass* wasting processes.	Same as above.
02	A4, A5	Debris fans; outwash fans; residual soils from weathered granitic and sedimentary rocks; glaciofluvial, deltaic, lacustrine, eolian deposits.	Step/pool & cascades.	High energy; high sediment supply; high sand bedload. Potentially high sediment storage behind LWD.	Bank erosion, channel rejuvenation common.	Same as above.
03	A6	Glacio-lacustrine; deltaic deposits; fine alluvium.	Step/pool & cascades.	High energy; high suspended washload; low bedload; low sediment storage.	Frequent collapsing of banks and bank erosion due to negative pore water pressure and liquefaction.	Same as above.
04	B1, B2, B3	Typically incised within narrow colluvial or structurally controlled valleys; coarse alluvium, colluvial materials, lag deposits from glaciation; *residuum from resistent lithologies.*	Step/pool; pools often erratically spaced, but at approx. 4-5 widths. Rapids predominate.	Moderate energy; low sediment supply; good sediment transport.	Very stable; aggradation and degradation processes are rare.	LWD important for creating pools for fisheries habitat. Discharges up to approx. 50 yr. RI inundate moderately wide *zone along stream.*
05	B4, B5, B6	Narrow valleys, often on rolling colluvial slopes, sometimes bounded by gently sloping pediments; associated with grussic granites, residual soils, aeolian deposits.	Step/pool; dominated by rapids and scour pools.	Moderate energy; low amounts of channel derived sediment; good sediment transport capacity; infrequent sediment deposition. Finer grained channels characterized by washload rather than bedload.	Finer-grained channels require good bank vegetation to maintain width/depth ratio.	Channels in good condition maintain pools; rapids maintain aeration. Discharges up to approx. 50-yr. RI inundate moderately wide zone along stream.
06	C1, C2	Bedrock within broad valleys; coarse deposition from past extreme flows.	Riffle/pool with pool spacing approx. 6-7 bankfull widths.	Moderate energy; high roughness due to coarse bed and meanders.	Adjusts laterally within adjacent floodprone areas; modern stream flows rarely entrain dominant bed materials.	Good connection with floodplain processes.
07	C3	Unconsolidated lag deposits or coarse colluvium within broad valleys.	Riffle/pool with pool spacing approx. 6-7 bankfull widths.	Moderate energy; moderate sediment supply.	Adjusts laterally, rates depends on type and extent of riparian vegetation.	Well-developed floodplain. Area frequently inundated by moderate floods maintains good *connection with riparian* vegetation process.

Table 2.9 (continued).

Stream Type Group Code	Individual Stream Types	Characteristic Landform, Geology	Bedform	Energy/Sediment Characteristics	Characteristic Mode of Adjustment	In-channel and Riparian Habitat Characteristics
08	C4, C5, C6	Broad alluvial valleys, often bounded by Holocene terraces, Valley fill is coarse alluvium to fine depositional materials (for example deltaic, lacustrine, ash, silts, clays).	Riffle/pool. Pool spacing approx. 5-7 bankfull widths.	Moderate energy; high sediment supply from channel. Sediment often redeposited within channel.	Adjusts both laterally and vertically in response to increased flows or loss of riparian vegetation. Bank erosion common, with accompanying lateral adjustments, and increases in width/depth ratio. Excessive sediment deposition can shift channel to braided form. Rates of adjustment depend on type and extent of riparian vegetation.	When in good condition represents "classic" meandering alluvial channel, with good connection to riparian vegetation and floodplain processes. Substrate is gravel to silts; pools can silt up if disturbed.
09	D3, D4 D5, D6	Broad alluvial valleys; associated with distributary channels, deltaic features, alluvial fans on steep terrain. Valley fill material varies from coarse to fine alluvium or lacustrine materials.	Closely spaced rapids and scour pools formed through converging &, diverging flows.	High energy, high sediment supply; very active deposition and erosion of channel bars.	Bank erosion and lateral adjustments occur frequently with runoff events. Aggradation via excessive deposition of longitudinal and transverse bars is common. Once established braided patterns tend to dominate modern river; unless upstream sediment supply is removed.	Pattern of rapids and scour pools is very unstable; runoff can disrupt spawning beds.
10	All DA	Broad, low gradient, tectonically active basins undergoing vertical accretion. Often associated with extensive wetlands in cohesive sediments.			Very stable; river builds silt-rich levies that often have herbaceous or forest vegetation. Channels respond to disturbance as individual channels. Adjustments are infrequent, but usually occur laterally, via channel avulsion or abandonment.	Numerous side channels, meanders, and accessible overwintering areas associated with wetlands and ponds. Good connection with riparian vegetation and floodplain processes.
11	E3, E4, E5, E6	Found at all elevations in broad alluvial valleys, although especially common in high mountain meadows.	Riffle/pool.	High energy at high streamflows. Low sediment supply (if riparian vegetation is present); very high sediment transport capacity.	Very stable in absence of disturbance; highly sinuous planform maintains bed elevation without downcutting. Increased flows or disturbance to banks can trigger adjustments via increases in width depth ratio, channel straightening, and increased channel gradient.	Shaded, undercut banks, generally fast flow. Good connection with riparian vegetation and floodplain processes.

Table 2.9 (continued).

Stream Type Group Code	Individual Stream Types	Characteristic Landform, Geology	Bedform	Energy/Sediment Characteristics	Characteristic Mode of Adjustment	In-channel and Riparian Habitat Characteristics
12	F1, F2	Deeply entrenched in bedrock or boulders within broad valleys or plains. Channel is often geologically old.	Riffle/pool.	Moderate energy; low sediment from bed and banks; low sediment deposition.	Very stable; often acts as upstream grade control.	Pools generally not as deep due to low sinuosity and trapezoidal channel form. Poor connection with floodplain due to entrenchment of channel.
13	F3	Entrenched in coarse depositional alluvium; often found in terrace-bounded alluvial valleys, deltas, and coastal plains.	Riffle/pool.	Moderate energy; dissipated against bed and entrenched banks. High bedload of coarse cobble/ gravel bedload. Some deposition of channel bars.	Active bank erosion adds to channel sediment supply. Channel bars are common and create hydraulic stress on banks.	Same as above.
14	F4					
15	F5, F6	Entrenched in sandy, lacustrine deposits; often found in terrace-bounded alluvial valleys, deltas and coastal plains.	Riffle/pool.	Moderate energy; dissipated against unstable, entrenched banks and bed. Very high channel-derived sediment; low bedload. Generally low sediment transport capacity.	Very unstable vertically and laterally. Bank erosion occurs via fluvial entrainment, mass wasting, bank saturation, and collapse. Sediment deposition is common; eventually creating a floodplain within the bankfull channel. Remainder sediment transported downstream. Banks composed of cohesive, fine-grained soils can be quite stable if deep-rooted riparian vegetation is maintained.	Same as above, except substrate is sand and silt. Disturbance can cause fining and siltation at site and downstream.
16	G1, G2	Incision into bedrock, narrow gorges; controlled by faults or joints; or within coarse alluvial fans, landslide debris; debris wedges below talus fields; colluvial deposits.	Step/pool with erratic spacing.	Moderate energy; high channel-derived sediments; high sediment transport capacity. Bedload often exceeds 50% of total sediment load.	Very stable channel; transfers watershed-derived sediment downstream.	Gully-like channel; poor connection with riparian vegetation or flood plain processes due to channel entrenchment.
17	G3,G4, G5,G6	Depositional, Unconsolidated cobbles, gravels sands; often associated with rejuvenated lateral tributaries through fluvial terraces.	Step/pool.	Moderate energy; high channel-derived sediments; high sediment transport capacity. Bedload often exceeds 50% of total sediment land.	Vertical and lateral instability; frequent degradation. Finer grained channels often cause grade control problems and are prone to excessive bank erosion.	Same as above; in addition disturbance can cause shifting and fining at site and down-stream.

themes used to stratify the Basin into areas having similar channel forming processes and, therefore, similar stream type group compositions included:

- Continuous geoclimatic subsection group maps that were used to describe similarities in climate, potential vegetation, and geomorphic processes and valley fill materials across the Basin.
- Classification maps of slopes by four classes (0-10%, 11-30%, 31-50%, >50%) that were displayed within each subsection group polygon.
- 1:100,000 hydrography intersected with the subsection group/slope class maps.

A panel of FS, BLM, NRCS, and USGS hydrologists (chosen on the basis of their familiarity with stream types and extensive field experience within the seven provinces of the Basin) reviewed this GIS product, and on the basis of their field experience estimated the composition of the dominant stream type groups that occurred within the four slope categories of each subsection group. The objective of this estimation procedure was to identify the probable distribution of dominant stream type groups throughout the Basin to discriminate among watersheds on the basis of their similarities and differences. No attempt was made to identify rare or locally "vulnerable" stream types in this assessment. Due to time constraints, the estimated distributions of stream type groups were not verified in the field or with existing data. These stream groupings, however, showed statistically significant differences among hydrologic subregions as classified on the basis of direct biophysical environment variables expected to influence channel form (Jensen and others in press). Stream type group compositions of subsection/slope class maps were associated by GIS to each 6th-field subwatershed of the Basin to facilitate subsequent hydrologic analysis of subbasins and subwatersheds.

The implications for management associated with the stream type groups used in this study follow Rosgen (1994) and are displayed in table 2.10. These resource interpretations include sensitivity of the channel morphology to increases in streamflow and sediment, the potential of the channel to recover following disturbance, the characteristic supply of suspended and bedload sediment from channel-derived sources and stream-adjacent slopes, streambank erosion potential, and the contribution of riparian vegetation to maintaining characteristic width/depth ratios (Rosgen 1994). For analysis purposes, these resource interpretations were converted to a numerical scale, as follows: very low (very poor) = 0, low (poor) = 25, moderate (fair) = 50, high (good) = 75; and very high (very good, excellent) = 100. The percent composition of each stream type group and its corresponding numerical ratings were used in assigning weighted average scores (that is, values from 0 to 100) to each subsection group/slope class setting. These values were then associated to each 6th-field subwatershed of the basin based on a weighted average of the subsection group/slope class composition (and their related scores) within each subwatershed (see Appendix 2A).

Ecological Process Interpretations

Various ecological process interpretations were associated to the different biophysical environment maps described in this document. The primary map themes used in associating this information to other biophysical environments (for example, 6th-field HUCs) were subsection/slope class maps for most soil erosion, mass failure, debris avalanche, and sediment hazard ratings; and subsection group/slope class maps for stream channel sensitivity and resiliency ratings. DEM data (90m) were used to create slope class (that is, 0-10%, 11-30%, 31-50%, and greater than 50%) vector maps of subsections and subsection groups in this analysis.

Information generated from the different types of ecological process modeling described below was summarized by 4th- and 6th-field HUCs for use in a variety of subbasin and subwatershed assessment efforts. A listing and brief description of the ecological process interpretations that were generated for each 4th- and 6th-field HUC in this project are presented in Appendix 2A of this chapter. Due to the fact that the types of information available to this project for calculation of many of the interpretations were not appropriate to landscape (or finer) levels of application, relative ratings of

Table 2.10—List of stream type groups identified within the Basin and their associated management interpretations (follows Rosgen 1994).

Stream Group Type	Stream Types	Sensitivity to Disturbance	Recovery Potential	Sediment Supply	Streambank Erosion Potential	Vegetation Controlling Influence

interpretive values were often calculated for broader scale use. Cumulative frequency distributions of actual 4th- and 6th-field HUC interpretation scores were calculated across different comparison areas in the development of the relative ratings (for example, each subwatershed was assigned a percentile number between 0 and 100 that reflected the percent of other subwatersheds within the comparison area that had an equal or lower value for a given type of interpretation). Comparison areas used in the generation of relative interpretation values included the Basin, geoclimatic provinces, ERUs, rangeland theme environments, and forestland theme environments.

The following is a brief description of the methods used in calculating biophysical environment-based ecological process interpretation ratings for the Basin.

Soil Erosion, Mass Failure, and Sedimentation

Various soil erosion, mass failure, and sediment hazard ratings were developed for each subsection following general procedures described in "An Approach to Water Resources Evaluation of Nonpoint Silvicultural Sources" [a procedural handbook (WRENS)] (Environmental Protection Agency 1980) with required modifications to facilitate use of general erosion/sediment process models at broader spatial scales. These hazard ratings and their primary input variables were also associated with each 6th-field watershed to facilitate development of affected environment descriptions and scenario projections of erosion and sediment processes by watershed classifications and ERUs. Such information was also used in developing descriptions of relative erosion and sediment hazard differences across the Basin. Use of absolute values concerning soil erosion and sediment was considered inappropriate due to the broad scale (such as subsections) at which these processes were modeled. Instead, the relative differences in these processes across the various subbasins or subwatersheds of a given comparison area (such as an ERU) were used in related assessment efforts. The following is a brief description of the approaches used in determining soil erosion, mass failure, and sedimentation ratings across the Basin.

Soil Erosion

Broad- and mid-scale analysis of surface soil erosion hazard used an approach similar to the U.S. Environmental Protection Agency's (EPA) Modified Universal Soil Loss Equation (MUSLE). In this model (EPA 1980), surface soil erosion in tons per acre per year was estimated based on slope/length (LS), soil erodibility (K), rainfall intensity (R), and vegetation management (cover) (VM). The vegetation management factor of the MUSLE was the only parameter that changed under the different alternatives and scenarios evaluated in this project. In the case of roads or large stand-consuming fires, the VM factor was set to 1 in MUSLE calculations (that is, no ameliorating effect from vegetation cover). The 90-meter DEM data were assigned to four slope classes (0-10%, 11-30%, 31-50%, and greater than 50%) and stored by midpoint of the slope classes in initial calculation of slope for the model. The slope/length factor (LS) of the MUSLE was assigned to each midpoint value using a default slope length of 90 meters. Slope classes were overlain on subsection maps to derive a vector map of subsection/slope phases for subsequent erosion predictions. This map served as the primary erosion modeling unit with other MUSLE variables attributed to this theme.

The soil erodibility factor (K) of the MUSLE was estimated for each subsection based on its dominant surficial geology and modified (if appropriate) based on local soil knowledge. Five classes of K values were used in this analysis. The rainfall factor (R) of the MUSLE used the long-term average 30-minute storm intensity that was displayed as a vector map. This map was obtained from the NRCS for this project. The baseline vegetation management (VM) factor of the MUSLE was

calculated based on canopy cover, ground litter cover, and ground bare soil cover values that were associated with broad-scale vegetation cover type classifications. Cover types, determined by using the Normalized Difference Vegetation Index from AVHRR satellite data, were used as baseline VM factor input (that is, version one of the broad-scale existing vegetation map was used in displaying cover types for erosion modeling). For the broad-scale analysis, estimated baseline erosion rates in tons per acre per year were summarized to subsection/slope phases and as weighted averages to 4th-field subbasins. These same parameters were used for mid-scale analyses; however, in this situation, weighted averages of subsection/slope phase values were associated to each 6th-field subwatershed.

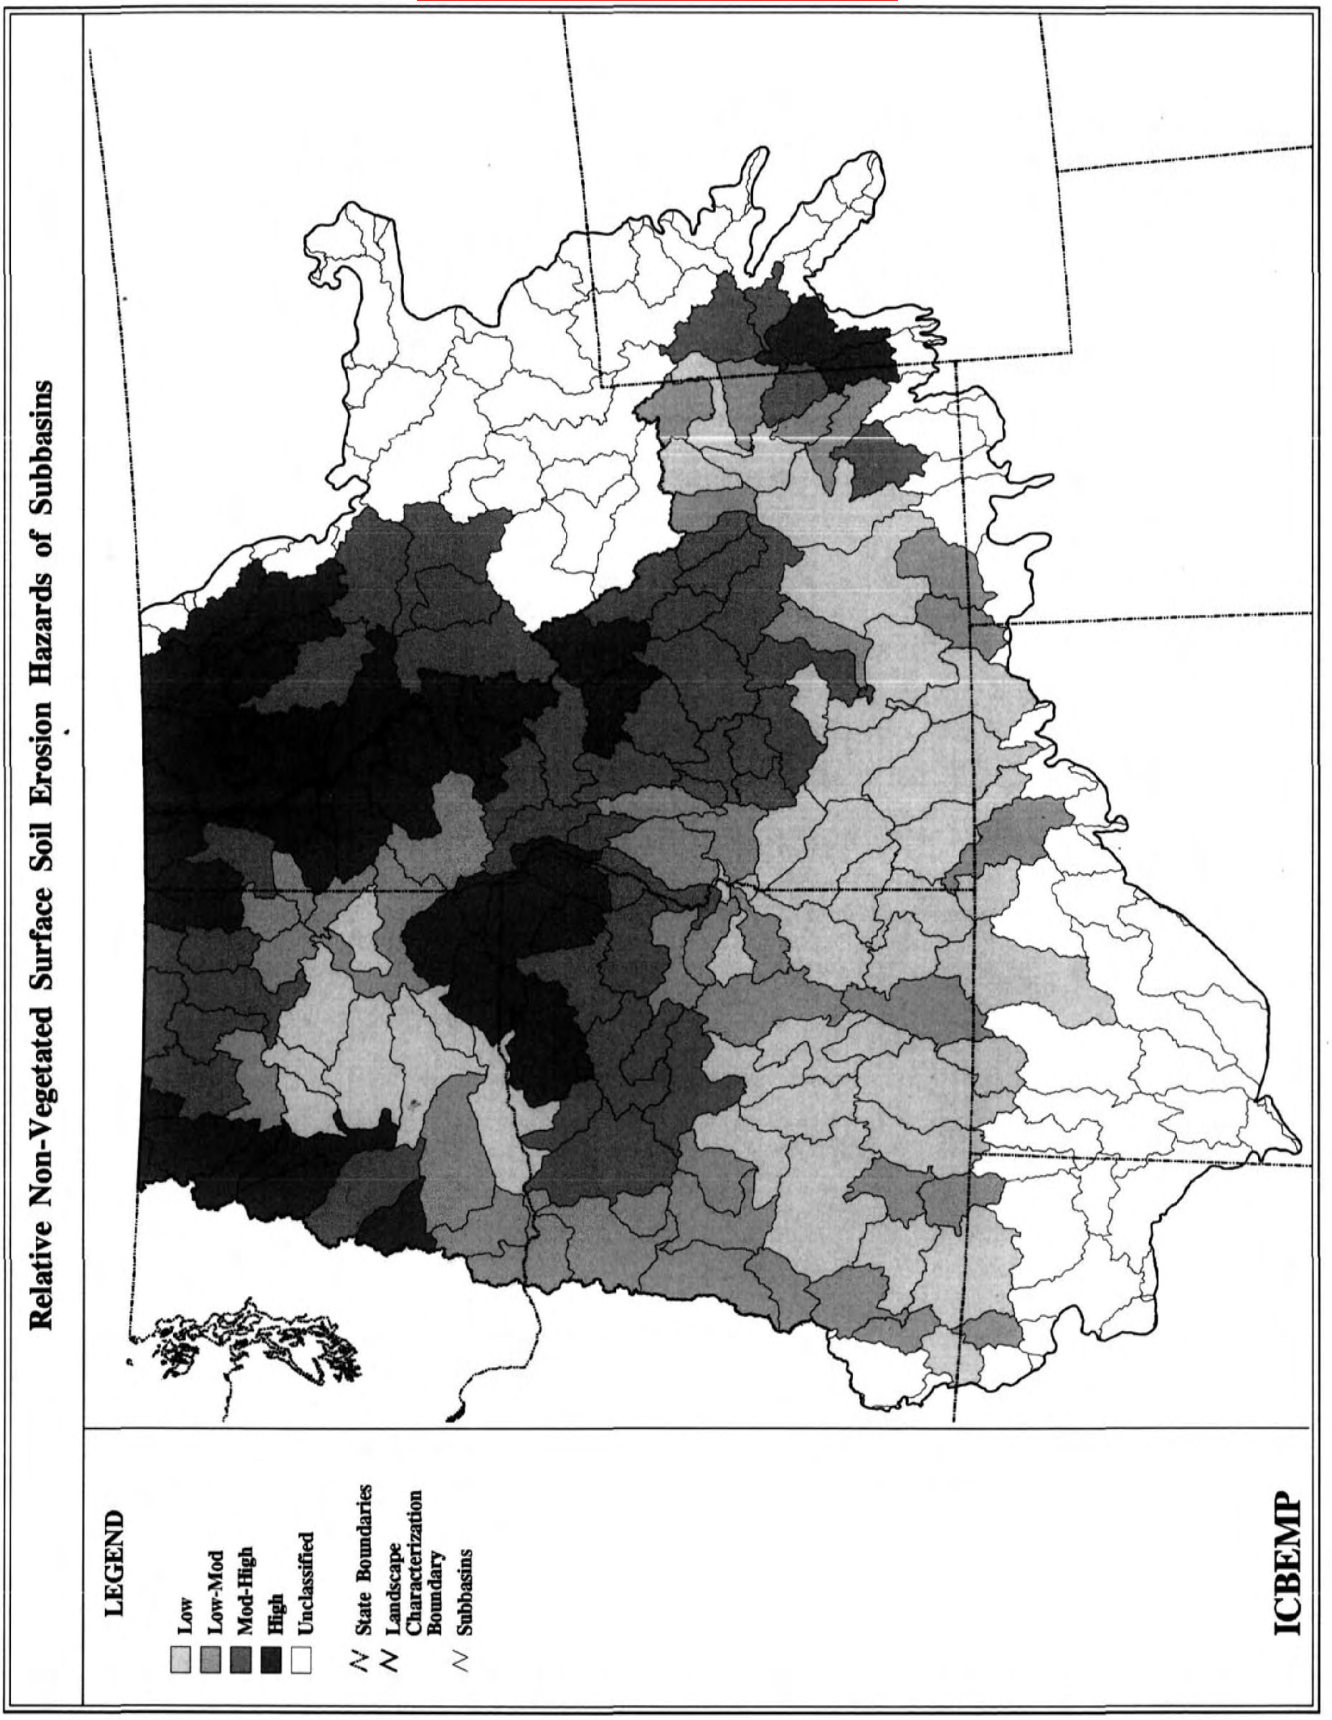
CRBSUM scenario projections for changes in vegetation cover type patterns were used to assign new vegetation management factors to each subbasin (4th-field HUC) or subwatershed (6th-field HUC) based on a weighted average of the vegetation types present. Erosion rates were recalculated to reflect changes in vegetation in such analyses. Average density of road networks were assigned to a watershed in some analyses, and the attributes for vegetation management (VM) were modified accordingly (that is, set to 1.0, no influence). Erosion rates were recalculated in terms of erosion rate per mile of road to reflect initial road density effects on surface erosion.

Road erosion hazard ratings were also calculated for each subbasin and subwatershed based on groupings of lithology and their relative erosion rates following road construction.

Various maps of relative soil erosion hazard were produced in this project for different types of assessment needs and contextual settings. For example, map 2.9 displays the nonvegetated surface soil erosion hazard of subbasins (4th-field HUCs) across the assessment area. In constructing this map, the actual value for this interpretation by each subbasin was converted to a cumulative frequency distribution percentile (that is, from 0 to 100), which expressed the percent of other subbasins within the Basin that had the same or smaller value for the interpretation. The classes displayed on this map are a grouping of these cumulative frequency numbers as follows: low (0-25), low to moderate (26-50), moderate to high (51-75), and high (76-100). A similar convention was used in producing the other relative interpretation maps.

The nonvegetated surface soil erosion hazard map (map 2.9) illustrates relative differences across the Basin when all vegetation cover is removed from a site. This type of characterization displays how erosion relations may change in an area following large-scale stand replacement fires. A more realistic description of current relative surface soil erosion differences across the Basin is illustrated in map 2.10 which considers existing vegetation cover in erosion hazard estimation.

Mass Failure



Broad- and mid-scale analyses of debris avalanches and earthflow hazards used similar parameters and approaches to those identified in surface soil erosion hazard analysis; however, parameter weights were adjusted to follow suggested WRENS procedures. Specific parameters used in earthflow hazard calculation included slope, probable soil texture and permeability, and average annual precipitation. Parameters used in debris avalanche hazard calculation included slope and average annual precipitation.

Baseline debris avalanche and earthflow hazard ratings were assigned to each subbasin and subwatershed of the Basin by overlaying the model output (that is, low, medium, and high hazard) to the base subsection/slope phase unit map and calculating a weighted average of these values for each subbasin and subwatershed. Relative differences in these hazard ratings across subbasins are presented on map 2.11 for earthflow and map 2.12 for debris avalanche.

Sedimentation

Broad- and mid-scale analyses of sediment delivery hazard were based on a potential sediment delivery index, which was used to adjust both nonvegetated and vegetated surface soil erosion hazard values to better reflect the probability of hillslope erosion reaching a stream network.

Sediment delivery potential indices were calculated for each subbasin and subwatershed of the Basin by:

- Overlaying the 1:100,000 scale hydrography map onto each subwatershed delineation and calculating its drainage density.
- Calculating the average slope of each delineation with 90-meter DEM data.
- Multiplying drainage density by the average slope of each delineation to obtain its initial sediment delivery index.

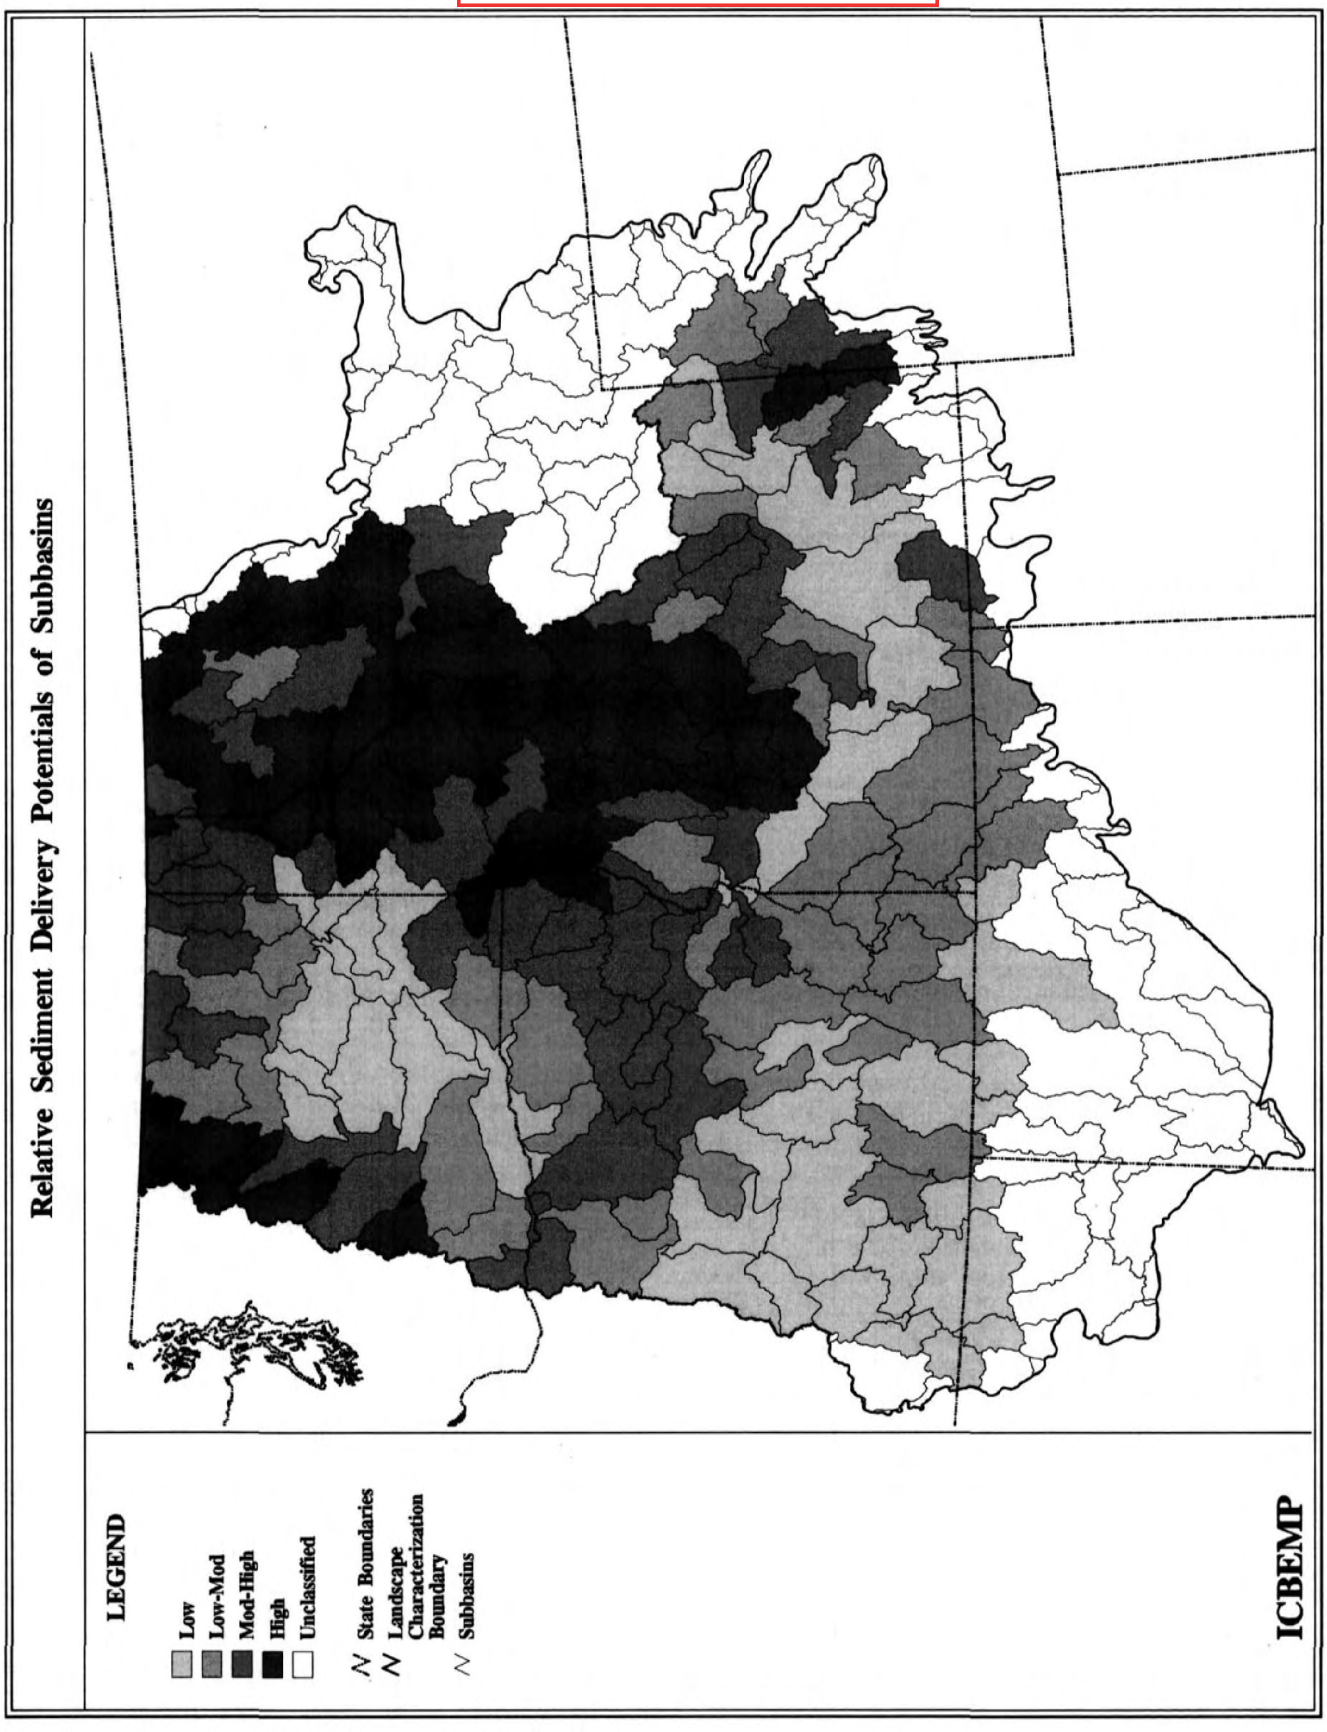
These HUC sediment delivery index values were, in turn, converted into a cumulative frequency distribution number between 0 and 100 that reflected the percent of other subbasins or subwatersheds with the same or lower index value.

These relative sediment delivery index scores were then multiplied by the average nonvegetated or vegetated surface soil erosion hazard value of each subbasin or subwatershed in determining its sediment delivery hazard. In this approach, the estimated erosion rate of an area was adjusted based on its steepness and dissection characteristics in the calculation of sediment that might possibly reach a stream. For example, areas with high hillslope erosion and gentle slopes with low dissection commonly displayed lower sediment delivery hazard scores than those with moderate hillslope erosion and steep slopes with high dissection. Relative differences in these ratings across subbasins are presented for sediment delivery potential (map 2.13), nonvegetated sediment delivery hazard (map 2.14), and vegetated sediment delivery hazard (map 2.15).

The road erosion hazard ratings mentioned above were also adjusted in this analysis based on relativized sediment delivery potential ratings. Map 2.16 displays the basic differences in road erosion hazard across the Basin based on the lithologic composition of each subbasin. These relationships changed, however, when road sediment delivery hazard was considered (map 2.17) due to the effects that slope and dissection have on sediment hazard ratings.

Hydrologic Function

Peak Flows



Streamflow discharges associated with frequent floods (those having recurrence intervals of approximately 1 to 10 years) strongly influence channel morphology, the interaction of the stream channel with its floodplain, and the temporal character of instream habitats (Eash 1993, Nash 1994, Poff and Ward 1989, Leopold and others 1963). In this analysis, several measures were used to characterize 6th-field subwatersheds in terms of flood flows and drainage characteristics. These measures included drainage density; the intensity of the expected 2-year, 24-hour storm event; and the expected discharge associated with a 10-year flood.

Drainage density affects the routing and timing of flood flows within a watershed. Relative drainage density characteristics were estimated from 1:100,000 hydrography for each of the approximately 7,500 6th-field subwatersheds within the assessment area. The 2-year return interval, 24-hour storm event describes the amount of precipitation that an area can be expected to receive within a 24-hour interval, every 2 years, on average. While this precipitation cannot be directly linked to a 2-year recurrence interval flood discharge, its use as an indirect, relative surrogate for a 2-year flood flow has been proposed for use in other watershed analyses (Eash 1993, Washington Forest Practices 1993). Regionalized flood equations applicable to the Basin have been developed (Jennings and others 1994), but do not include

estimation methods for a 2-year flood flow continuously across the Basin. Consequently continuous estimation of the 2-year return interval 24-hour rainfall developed from weather atlases (Miller and others 1973) was used as a surrogate measure in this analysis. Within the study area, the depth of the estimated 2-year 24-hour rainfall varied from 1.8 centimeters in the Columbia Plateau and the Snake River Plain, to 17.8 centimeters along the eastern crest of the Cascade Mountains.

In describing flood discharges most associated with channel morphology and flood plain interactions in this study, Nash (1994) calculated the discharge associated with the 10-year recurrence interval flood for the pour-point of each subwatershed within the Basin using regionalized regression equations (Jennings and others 1994). Within the study area, the streamflow discharge associated with the 10-year flood event varied from 1.42 cubic meters per second in certain subwatersheds within the interior of the Basin, to 124.52 cubic meters per second for some subwatersheds located along the Snake and Columbia Rivers.

Drainage density, 2-year 24-hour storm event, and estimated 10-year flood discharge values were attributed to each subwatershed for use in hydrologic subregion classification efforts. Each of these variables was found to be highly significant in explaining variations in valley bottom forms and stream types within the hydrologic subregions identified for the Basin (Jensen and others in press).

Runoff Characteristics

Streamflow characteristics control many important structural attributes of streams, such as habitat volume, current velocity, channel morphology, substrate stability, and inundation of floodplains (Poff and Allen 1994). Streamflow fluctuations and overbank flows are the primary sources of environmental variability and disturbance to stream environments (Stanford and Ward 1983).

To estimate the reference variability of streamflow conditions, this analysis characterized the streamflow regimes of 128 gauge stations within the Basin. These stations were selected because they represented, as nearly as possible, unregulated streamflow regimes and because they had daily streamflow data over at least a 20-year period of record.

Fourteen measures of streamflow variability were calculated for this analysis:

- Baseflow index (defined as the ratio of the lowest daily flow to the average daily flow).
- Coefficient of variation in flow (defined as the average of the ratios between annual mean daily flow and the standard deviation of daily flows).
- Predictability of flow (an index of constancy and periodicity of flows).
- Flood frequency (defined as the average number of discrete flood events per year having a magnitude equaling or exceeding the discharge associated with an expected recurrence interval of 1.67, based on a log-normal distribution using annual peak flows). This flood frequency is often associated with bankfull stage, but such stage may vary regionally and with climate.
- Interflood interval (defined as the average number of days between individual flood events).
- Flood duration.
- Seasonal predictability of flooding (defined as the maximum proportion of floods over the period of record that fall in any 60-day "seasonal window").
- Timing of flooding (the day of the water year marking the beginning of the 60-day period having the most predictable floods).
- Seasonal predictability of non-flooding.

- Extent of intermittent flow.
- Low flow frequency (defined as the average number of discrete low flow events per year having a magnitude less than a 5-year low flow value).
- Seasonal predictability of low flows.
- Timing of low flows.
- Seasonal predictability of non-low flow [defined as the maximum proportion of the year (number of days divided by 365) during which no greater than 5-year return interval low flows have ever occurred over the period of record].

Multivariate statistical methods (Poff and Allen 1994, Poff and Ward 1989) were used to classify the streamflow regimes from 128 gauge sites into five categories:

- 11 groundwater-dominated streams
- 55 snowmelt streams
- 40 rain on snow streams
- 22 winter rain streams
- 1 harshly intermittent stream

The high degree of engineered alterations, such as dams and water diversions within certain streams precluded the use of all gauge sites for the Basin in the characterization of streamflow regimes. Specifically, appropriate gauge stations were unavailable for the Southern Cascades ERU, Upper Klamath ERU, Northern Great Basin ERU, and Snake Headwaters ERU. In addition, the existing locations of appropriate gauges for analysis precluded characterization of watersheds of similar spatial scales. Despite these facts, the streamflow analyses conducted in this study revealed significant differences among streamflow regimes. Across the Basin, these differences included:

- Snowmelt, snow plus rain, and winter rain streamflow regimes had much higher flow regime coefficients of variation than did groundwater-dominated regimes.
- The daily streamflow of groundwater and snowmelt streams was more predictable than snowmelt and winter rain streams.
- Snow and rain streamflow regimes had higher median flood frequencies.
- Snowmelt streams had much higher seasonal predictability and the greatest flood-free period.
- Flood timing was clearly different between snowmelt streams (floods begin about May), rain-on-snow streams (floods begin in March to April), and winter rain streams (floods begin in December and January).
- Groundwater streams displayed the greatest variability in flood timing values (although not significantly different than the other runoff categories studied).
- Groundwater-dominated streams possessed the highest baseflow index, followed by snowmelt streams, winter rain streams, and rain on snow streamflow regimes.

Results of this streamflow analyses were used in the description of ERUs. These results were also used in an independent test of the hydrologic region classification that was developed based on biophysical environment similarities between 4th-field subbasins.

Stream Channel Sensitivity and Resiliency Ratings

Various stream channel sensitivity and resiliency ratings were developed to facilitate comparison of relative differences in subbasins and subwatersheds at Basin, ERU, and hydrologic subregion levels of analysis. All of these ratings were derived from the estimated composition of Rosgen (1994) Stream Type Groups within each subbasin and subwatershed (see above discussion concerning Stream Type Settings).

The weighted average scores of these resource interpretations (see table 2.10) by individual subwatershed were used to generate the hydrologic interpretation ratings described below. The following is a listing of stream channel sensitivity and resiliency ratings calculated in this analysis:

- Sensitivity to increased sediment and flow at a site.
- Sensitivity to increased sediment and flow downstream from a site.
- Sensitivity to decreased sediment and flow at a site.
- Sensitivity of streambanks to disturbance.
- Sensitivity (or dependency) of channel form to adjacent riparian vegetation.
- Recovery potential following disturbance.

Cumulative frequency distributions of average subwatershed resource interpretation scores were calculated across different comparison areas in the development of hydrologic sensitivity and resiliency ratings for this study (that is, each subwatershed was assigned a number between 0 and 100 that reflected the percent of other subwatersheds within a comparison area that had an equal or lower value for a given type of interpretation).

Maps of these relative ratings were then produced that displayed class groupings of cumulative frequency scores as follows: low (0-25), low to moderate (26-50), moderate to high (51-75), and high (76-100). Examples of these relativized hydrologic sensitivity and resiliency ratings across the Basin are provided in maps 2.18-2.21. A master watershed sensitivity index was also calculated for each subwatershed used that was based on the combined relative scores of sediment hazard without vegetation and stream recovery potential. This rating is displayed by subbasins across the Basin in map 2.22.

Vegetation Response to Climate Change

A critical part of any ecological assessment is the determination of biotic distributions and biotic-environmental relations. Rarely, however, are complete inventories of the biota within an area of interest available to managers. Statistical methods have been developed to predict biotic distributions based on correlation of biotic responses to environmental attributes. Application of developed models results in:

- Quantification of the response of species and communities to environmental driving variables.
- The ability to predict biotic distributions over unsampled areas.
- The ability to predict the effects of environmental changes on biotic distributions over large areas.

To construct effective models, environmental variables that directly constrain the distribution of species are first described. These variables are termed driving variables and include thermal, moisture, radiation, and nutrient regimes. The class of statistical models known as generalized linear models are commonly used to predict species responses to driving variables in this type of analysis (Nicholls 1989).

To assess current and predicted ecological conditions in the Basin, it was necessary to have maps of continuous distribution maps of species and communities over the entire analysis area. Such maps however, generally did not exist for the Basin or did not provide for the prediction of future distributions under a given scenario of environmental change. Therefore, the results of predictive modeling of biotic responses to climate attributes were required to map distributions of selected species and communities under current and predicted climate change in this study.

Modeling Approach

The biotic information used in modeling vegetation response to climate change consisted of presence or absence data for selected species and communities. A vegetation plot database (ECADS) that had approximately 38,000 spatially located plots assembled for this assessment was used in this modeling effort. The membership of a plot in a given class (community) was determined using threshold canopy cover levels of diagnostic species.

Map 2.21—Relative stream recovery potentials as summarized by subbasins.

Map 2.22—Master watershed sensitivity index of subbasins.

Thresholds were derived from information contained in the existing vegetation classification (Bourgeron and Engelking 1994) used in potential vegetation mapping. Four plant species and four plant communities were selected for this predictive modeling effort in consultation with the SIT Terrestrial Staff. Species were chosen from among those listed as used by Native Americans in the interior Pacific Northwest, and included a tree, Ponderosa pine *(Pinus ponderosa),* and three shrubs: blue huckleberry *(Vaccinium membranaceum/V. globulare),* chokecherry (*Prunus virginiana),* and serviceberry *(Amelanchier alnifolia).* Communities studied included Western redcedar/queencup beadlilly *(Thuja plicata/Clintonia uniflora),* ponderosa pine/common snowberry *(Pinus ponderosa/Symphoricarpos albus),* big sage *(Artemisia tridentata)* series, and subalpine fir/bluejoint *(Abies lasiocarpa/Calamagrostis canadensis).*

Environmental variables used in species distribution modeling included daily values for temperature, precipitation, and solar radiation, which were available for a normal year (1989) and for a climate change scenario (doubled CO_2) over the assessment area at a 2 km^2 cell size (Thornton and Running 1996; Thornton and others, in press). These daily values were combined into nine climate attribute predictor variables in this study: annual average temperature, maximum July temperature, minimum January temperature, annual precipitation, winter precipitation (January-March), spring precipitation (April-June), summer precipitation (July-September), fall precipitation (October-December), and annual solar radiation. Plot locations (accurate to within 2 km) were used to assign values for the climate attribute values to each plot with a GIS ARCINFO software.

Predictive models of species or community presence or absence were developed using a generalized linear model formulation appropriate to binomial distributions. Model structures consisted of a linear combination of environmental attributes linked to the predicted response by a nonlinear logic function that constrained predicted values between 0 and 1 (McCullagh and Nelder 1989). Models of biotic response were constructed using a forward stepwise procedure in which, at each step, a climate attribute was selected whose addition to the model produced the largest significant change in deviance. A one percent significance level was used as the criterion for adding an attribute to the model. Attributes could enter as either linear or linear plus quadratic terms. The significance of interactions between attributes and for the addition of cubic terms was also tested.

Predicted distributions of the four species and four communities studied were generated under current climate conditions and for the climate change scenario using modeling results. Equations were applied to GIS outputs of the nine climate attribute values for each 2-km^2 cell. Results were displayed in two ways:

- Probabilities of occurrence were mapped as one of four classes (0 to 0.25, 0.26 to 0.50, 0.51 to 0.75, and 0.76 to 1.00) to reflect probability statements about the distribution of species and communities.
- Probabilities were converted to presence or absence values for mapping.

Model accuracy was assessed by constructing "confusion" matrices indicating numbers and percentages of plots falling within one of the following four categories. A species or community was:

- Observed and predicted to be present (correct prediction).
- Observed and predicted to be absent (correct prediction).
- Observed present and predicted absent (incorrect prediction).
- Observed absent and predicted present (incorrect prediction).

Modeling Results

Among the four species models, the percentage of plots in which the presence or absence of a species was correctly predicted varied from 68 to 76 percent. Three climate attributes were significant predictors in

all four models: annual average temperature, spring precipitation, and summer precipitation. All species models contained interaction terms and only the model for *P. virginiana* lacked a cubic term for at least one climate attribute (indicating a skewed response).

Three of the four community models were successful in predicting community presence or absence. Correct prediction varied from 80 to 85 percent for *T. plicata/C. uniflora, P. ponderosa/S. albus,* and *A. tridentata* series. A lower percentage of correct predictions was observed for *A. lasiocarpa/C. canadensis* (63%). The distribution of a riparian community such as *A. lasiocarpa/C. canadensis* may be determined by environmental attributes not included in the model, such as subsurface soil moisture. In addition, the 2-km^2 cell size used to estimate climate attributes is probably too broad a scale to represent riparian and wetland conditions. Three of four community models included a climate attribute as a cubic function, and one model contained an interaction term.

Four maps were produced for each species and community studied: predicted probability class and presence/absence under current climatic conditions, and predicted probability class and presence/absence under the doubled CO_2 climate change scenario. Probability class maps are shown for the community *T. plicata/C. uniflora* for current (map 2.23) and climate change (map 2.24) conditions. The predicted distributions of all species and all communities, except *A. lasiocarpa/C. canadensis,* were in general agreement with known occurrences, although prediction errors were also detected. In many cases, errors in predicted distributions could be attributed to the influence of environmental factors not included in the models, such as the effect of geological substrate, which was not available as a regional map when modeling was performed. The distribution of *A. lasiocarpa/C. canadensis* was systematically overestimated throughout the area.

Changes in predicted biotic distributions under doubled CO_2 included both range expansions, (for example, *V. membranaceum/V. globulare* and *T. plicata/C. uniflora)* and range contractions, (for example, *P. virginiana* and *A. tridentata* series) that such changes were considered to indicate that an increase in mesic conditions would generally be found across the climate change scenario modeled. Results suggest that simple species/environment relationships (for example, bell-shaped responses), frequently accepted as appropriate by land managers and scientists, should be used with caution in devising management strategies. Modeling results also demonstrate the importance of the environmental attributes used in analysis and the scale at which they are estimated. For example, species and communities may respond to environmental attributes not included in modeling and/or attributes at a finer scale of resolution.

Development of Ecological Reporting Units

Early in of the Interior Columbia Basin Ecosystem Management Project, both the Science Integration Team and the EIS Team recognized the need for a strategy to subdivide the Basin into geographic areas or provinces to facilitate integrated reporting of assessment results. The first version of the project's "Scientific Framework" addressed the potential utility of provinces as a means "to facilitate assessment, decision making, monitoring, and dissemination of information at a finer scale... Also, provinces can facilitate multi-agency, multi-ownership, multi-government collaboration." (Eastside Ecosystem Management Project, Science Integration Team 1994). The term "province" is used in the "Scientific Framework" generically as any subunit of the Basin. The Northwest Forest Plan (1993) also uses the term "province" as does the *Ecological Subregions of the United States: Section Descriptions* (McNab and Avers, compilers 1994). The province system in the Northwest Forest Plan is a watershed-based delineation for western Washington and Oregon and for northern California. The province system in *Ecological Subregions of the United States* is the third level of the Forest Service national hierarchical framework of ecological units. To avoid confusion regarding other uses, intents, and definitions of the term "province," the Science Integration Team decided to use the term

Map 2.23—Predicted distribution of *Thuja plicata/Clintonia uniflora* plant communities under current climate conditions.

Map 2.24—Predicted distribution of *Thuja plicata/Clintonia uniflora* plant communities under a doubled CO_2 climate change scenario.

"Ecological Reporting Unit (ERU)" to refer to the geographic subdivisions of the Basindescribed in this section. These ERUs were constructed to facilitate common reporting of ecological assessment results by various science team staffs at a broad level (that is, regional and subregional assessment scales).

As discussed earlier in this document, geology and climate are some of the principal factors that influence ecosystem patterns and processes at broader analysis levels (for example, regional and subregional assessment scales). Climate supplies energy and water to all ecosystems, and geologic structure supplies the material from which the forces of climate carve landforms and form soils (Lotspiech 1980). Vegetation patterns, in turn, are largely determined by these coarser level components of the biophysical environment. The geoclimatic properties of river basins and subbasins, in a similar manner, influence the physical processes (such as flooding and mass wasting) and finer-scale physical patterns (such as stream types and channel units) that create habitat for aquatic species. Given these relations, importance was placed on the use of biophysical environments (such as geoclimatic sections and hydrologic regions) in the identification of ERUs for various science team assessment efforts.

The identification and delineation of ecological reporting units in the ICBEMP was an "integrated" exercise accomplished via participation of all disciplines on the ICBEMP Science Integration Team. The final ERU map produced in this project resulted from an integration of three primary map themes through a series of iterative steps, which are described below.

The first map theme considered in ERU delineation emphasized terrestrial ecosystem components and was based primarily on the section and subsection delineations described in this document. These delineations were, however, adjusted to follow the nearest 6th field subwatershed boundary in this effort.

The second map theme considered in ERU delineation emphasized human uses of ecosystem components and was based primarily on socioeconomic criteria attributed to counties. Grouping of counties into geographic clusters for mapping was based on the dominant human use of natural resources, as well as some selected biophysical factors that related to human use of the land. These geographic clusters were displayed by county boundaries and state lines in map preparation.

The third map theme considered in ERU delineation emphasized aquatic ecosystem components and was based primarily on a regional classification of 4th-field hydrologic units with similar hydrologic characteristics and geoclimatic properties. This map theme approximated the distribution of aquatic species as determined by zoogeographic province data.

These three map themes provided remarkably similar delineations which were integrated (through visual inspection) following 6th-field subwatershed boundaries in ERU map theme construction (that is, coincident lines were adjusted to follow subwatershed boundaries). The final ERU map produced for the Basin identified 13 settings that are listed below and discribed later in this chapter. These ERUs were used extensively by various science team staff in describing biophysical environments, ecological processes, effects of management activities, and landscape management opportunities.

- Northern Cascades
- Southern Cascades
- Upper Klamath
- Northern Great Basin
- Columbia Plateau
- Blue Mountains
- Northern Glaciated Mountains
- Lower Clark Fork
- Upper Clark Fork
- Owhyee Uplands
- Upper Snake
- Snake Headwaters
- Central Idaho Mountains

Description of Basic Ecosystem Components

Geology Features

A general characterization of selected geologic information by ERU is provided in table 2.11. Given the diversity of rock types, ages, and other properties of the geologic environments within the Basin, the classifications listed in table 2.11 should be viewed as simplified generalizations and approximations. Many substantial geologic patterns and processes that are common to all ERUs or are of limited areal extent are not listed in this table. For example, erosion and sedimentation are processes that occur in all ERUs; however, calculations of actual rates are dependent on local variables outside the range of this discussion. Additionally, most industrial minerals are not listed because sand and gravel deposits are important in all ERUs. Locally important products such as stone, abrasives, and zeolites were not addressed in the mineral resource assessment of the Basin (Box and others, in press).

Geologic Processes

Geologic processes and their interaction with atmospheric and hydrologic processes operating at many spatial and temporal scales have shaped, and continue to shape, the landscapes of the Basin. Recognition of the role of geologic processes and their rates provides a needed context in understanding the role of human-induced changes in any ecosystem. At the broadest scale, sea-floor spreading and continental drift [2 to 15 centimeters(cm)/yr] determine the locations and physiography of the continents. Intermediate-scale geologic processes operate at temporal scales of tens of millions to thousands of years and represent responses of the earth's crust to the larger forces of plate tectonics. Examples of intermediate-scale geologic processes include faulting, volcanism, and mountain building. These intermediate-scale processes formed the physiography of the Basin which, in turn, interacted with atmospheric processes to create the climatic conditions, landforms, and drainage patterns present today.

At the scale of a watershed and valley bottom, the processes operable during the Pleistocene ice ages [1.6 million to 10,000 years Before Present (B.P.)] have greatly influenced the topography and surficial materials seen today. At a finer scale of hill slopes and channels, modification of physiography is controlled primarily by recent (last 10,000 years) geomorphic processes. Catastrophic processes or disturbances (for example, volcanic eruptions, floods, landslides, and earthquakes) that last from minutes to days have continually modified the current physiography and drainage patterns of the Basin throughout geologic history and continue to influence the system today. Most geologic processes that directly affect the current structure, function, and composition of Basin ecosystems tend to be catastrophic. On a human time scale, such processes occur infrequently but cause substantial change in affected areas. These processes include individual volcanic eruptions, earthquakes, floods, land movement, and large-scale erosion and sedimentation. Although these processes cannot be managed, responses to them can be planned.

Changes in the rate of geologic processes that may be caused by human activities can be recognized and accounted for in land management planning. For example, human-induced changes to land surfaces have increased erosion rates and altered evapotranspiration rates, water movements, and toxic element fluxes in some areas of the Basin. Additionally, point-source increases in toxic element flux (including both metals and acidic or other chemical drainage) and increased sedimentation may result from future development of renewable and non-renewable resources, recreational development, urbanization, and agricultural practices within the Basin.

Table 2.11—Geoclimatic characteristics of ecological reporting units.

ERU	Landforms	Bedrock & Surficial Material	Elevation Range (m)	Mean Annual Precip. & Temp.	Major Potential Vegetation Groups
North Cascades	Glaciated and unglaciated mountains; with some hills, plains, buttes and plateaus.	Crystalline rocks: granitic, gneiss, schist, serpentine, volcanic rocks, sedimentary rocks; glacial, fluvial and mass wasting deposits.	600-2,896	250 to 4,000 mm 1 to 9° C.	Ponderosa pine, Douglas-fir and sagebrush; white fir and western red cedar; silver fir and mountain hemlock.
South Cascades	Mountains, plateaus, lava plains, buttes, shield volcanos, and some high elevation glaciation.	Volcanic and sedimentary rocks; ash, and pumice.	91-2,743	250 to 3,000 mm 2 to 10° C.	Ponderosa pine, Douglas-fir, sagebrush, white fir, and silver fir.
Upper Klamath	Mountains, plateaus, rolling hills, floodplains, and terraces.	Metamorphic and volcanic rocks, and alluvium.	1219-2,438	300 to 875 mm 4 to 10° C.	Sagebrush, ponderosa pine, Douglas-fir, white fir, red fir, and silver fir.
Northern Great Basin	Basin and range.	Volcanic rocks.	1,200-2,200	100 to 790mm 5 to 10° C.	Salt desert shrub, sagebrush, and juniper.
Columbia Plateau	Plateaus, hills, and plains.	Basalts and volcanic rocks; loess, glacial outwash, and flood deposits.	61-1,220	180 to 450 mm 4 to 14° C.	Sagebrush, and bluebunch wheatgrass Idaho fescue.
Blue Mountains	Dissected plateaus, foothills, mountains, canyons, and valleys.	Granitics, metamorphics, volcanics, and serpentenite.	300-3,300	230 to 460 mm -2 to 11° C.	Sagebrush, grasslands, ponderosa pine, Douglas-fir, grand fir, and minor subalpine fir.
Northern Glaciated Mountains	Glaciated mountains, foothills, basins, and valleys.	Granitic, gneiss, schist, siltite, shale, quartzite, carbonate; glacial till, and outwash.	244-3,081	410 to 2,540 mm -1 to 14° C.	Douglas-fir, ponderosa pine, grand fir, western hemlock, and subalpine fir.

Table 2.11 (continued).

ERU	Landforms	Bedrock & Surficial Material	Elevation Range (m)	Mean Annual Precip. & Temp.	Major Potential Vegetation Groups
Lower Clark Fork	Dissected mountains, breaklands, foothills, and valleys; some alpine glacation.	Metasedimentary, granitic metamorphic carbonate rocks.	366-2,135	1,020 to 2,030 mm 2 to 7° C.	Douglas-fir, ponderosa pine, grand fir, western red cedar, and subalpine fir.
Upper Clark Fork	Glaciated and unglaciated mountains; valleys, and canyons; glacial and lacustrine basins.	Granite, gneiss, schist, sandstone, shale, carbonate, and rocks.	915-3,111	360 to 2,030 mm 2 to 8° C.	Grassland, sagebrush, Douglas-fir, ponderosa pine, and subalpine fir.
Owyhee Uplands	Dissected mountains, plains, plateaus, and foothills.	Volcanic basaltic flows and pyroclastic rocks.	641-2,501	200 to 400 mm 2 to 8° C.	Salt desert shrub, sagebrush, and juniper.
Upper Snake	Basins, valleys, mountains, plateaus and plains.	Volcanic- basalt to rhyolite; and carbonate, phosphate, clastic sedimentary rocks.	397-2,288	100 to 790 mm 4 to 13° C.	Salt desert shrub, sagebrush, and juniper.
Snake Head Waters	Overthrust mountains, valleys, foothills, and basins.	Volcanic- basalt to rhyolite; and carbonate, phosphate, clastic sedimentary rocks.	1,524-4,202	400 to 1,015 mm 2 to 7° C.	Douglas-fir, lodgepole pine, sagebrush, and subalpine fir.
Central Idaho Mountains	Dissected mountains, breaklands, canyons, basins, foothills, and valleys, and some alpine glaciation.	Granitics, gneiss, schist, shale, carbonate rocks, and volcanic rocks.	427-3,861	250 to 2,030 mm 3 to 10° C.	Douglas-fir, grand fir, sagebrush, grasslands, and subalpine fir.

Plate tectonics—The oldest rocks of the Basin include granite and gneisses in western Montana and Wyoming that cooled and crystallized deep within the earth as long as 2.7 billion years ago (Hoffman 1989). The Belt basin, in the eastern portion of the Northern Glaciated Mountains (ERU 7), formed by rifting and subsidence of the older granitic and gneissic rocks of the continental crust over 1.5 billion years ago. The sediments that filled the resulting basin formed a thick sequence of siltstones, quartzites, and carbonates that are now exposed at the surface in part of ERU 7. During the Late Cretaceous Period, about 100 million years ago, continental and oceanic crustal fragments were joined to the western edge of the North American continent; the trace of this junction now lies in western Idaho (Oldow and others 1989). This junction is buried under younger rocks in southern Oregon and Washington and has been deformed by subsequent tectonic events. All rocks west of this junction (that is, rocks located in ERUs 1-4, 6, and parts of 5, 7, and 10) have been added to the continent by plate tectonic processes in the last 100 million years.

Volcanic processes and hazards—Volcanism has been and continues to be a profound agent of change for the landscapes of the Pacific Northwest. Volcanic rocks underlie most of the assessment area in southern Washington, Oregon, and southern Idaho (ERUs 1-6 and 10-12).

Arc volcanism, which is the process that leads to construction of linear chains of cones and flows such as the volcanic Cascade Mountains (ERUs 1-3), has occurred continually for at least 25 million years. Arc volcanoes form in response to subduction, which is the overriding of oceanic crust by the edge of the continent. The physiography of the Cascade Mountains (ERUs 1-3) is the result of the eruption of lava flows, domes, and cones from the hundreds of volcanoes in the Cascade arc. Eruptions of Glacier Peak, Mt. Mazama, and other Cascade mountain volcanoes have deposited extensive blankets of volcanic ash throughout the Basin (Sarna-Wojcicki and Davis 1991).

The eruption of Mt. Mazama about 7,000 years ago dispersed about 120 cubic kilometers of tephra over the entire Basin (Bacon 1983). Compacted unconsolidated volcanic ash (tephra) deposits from the Mazama eruption are as thick as 50 millimeters (mm) at 1,000 kilometers east of the crater and as thick as 4 meters at 20 kilometers from the crater (Hoblitt and others 1987). Lahars (volcanic mud flows) may also affect large areas and may be caused by very small eruptions. Melting of large volumes of glacial ice from volcanic eruptions may produce deposits that travel many kilometers downstream and can blanket large areas with deposits of mud.

During the last 4,000 years, volcanoes of the Cascade mountains have erupted, on average, twice per century (Dzurizin and others 1994). Such return frequencies are also similar to those associated with very large forest fire events. The tephra deposits of these volcanoes are easily eroded. Management practices in areas underlain by such ash deposits may greatly affect erosion and sedimentation rates. Tephra deposits also modify the water-holding capacity of soils into which they are incorporated. Additionally, tephra deposits typically provide a readily available source of mineral nutrients to terrestrial and aquatic ecosystems. The glassy nature and fine-grain size of volcanic ash permits rapid chemical weathering of its mineral components and release of contained nutrient elements for uptake by plants (Gough and others 1981).

About 1 km^3 of tephra was ejected from the volcanic eruption of Mt. St. Helens on May 18, 1980 (Sarna-Wojcicki and others 1981). Areas nearest the volcano were most affected by this eruption and currently provide a natural laboratory for the study of ecosystem response to disturbance. The pyroclastic surge of the eruption of Mt. St. Helens leveled trees as far as 28 kilometers from the crater and affected an area of 600 square kilometers (Moore and Sission 1981). Ash from the main eruption of Mt. St. Helens and subsequent eruptions was deposited over most of eastern Washington and much of central Idaho and western Montana (ERUs 1, 5, and 8). Ash deposits in

Ritzville, Washington, 175 kilometers northeast of the volcano, were as thick as 50 millimeters (Sarna-Wojcicki and others 1981). The landslide and proximal deposits from this eruption filled most of the Spirit Lake Basin on the north side of the mountain and raised the lake's surface about 61 meters (Voight and others 1981).

Lahars and floods caused by the Mt. St. Helens eruption and by rapid melting of glaciers and snow pack on the mountain affected both aquatic and riparian environments and the human populations living in the floodplains on the north side of the mountain (Janda and others 1982). The re-establishment and development of both aquatic and terrestrial communities following this eruption has been rapid. An excellent compendium of papers on the volcanic processes and short-term effects of the 1980 eruption of Mt. St. Helens is contained in Lipman and Mullineaux (1981). Although the site, size, and time of the next volcanic eruption from the volcanoes of the Cascade mountains cannot be predicted, such events will continue to occur sporadically in the foreseeable future.

Estimated likelihoods of tephra deposition of 1 centimeter thicknesses in a single year vary from 1 in 100 in the Cascades ERUs (1, 2, and 3), to less than 1 in 1,000 in the eastern part of the Basin. The likelihood of thicker deposits in a single year are correspondingly lower (Hoblitt and others 1987). Although there is little likelihood for thick deposits of ash in any given location in the western part of the Basin in a given year, it is certain that within a 200-year timeframe there will be a substantial eruptions within or adjacent to the Basin. The eruption from Mt. St. Helens in 1980-1985 deposited ash over an area equal in size to Washington State; furthermore, eruptions of the size of Mt. Mazama blanketed the entire Basin and beyond. Although the probability of very large eruptions in any given year is low, the potential effects of such an eruption would be substantial to all physical, biological, and social components and processes of the Basin.

The Columbia River basalts form the cliffs of the central Columbia plateau (ERUs 5 and 6) in southern Washington, northern Oregon, and western Idaho. These flood basalts erupted between 17 and 6 million years ago; however, approximately 95 percent of the 174,000 cubic kilometers of basalt were erupted within a 2-million year time period (Swanson and others 1979, Tolan and others 1989). These basalts represent gigantic outpourings of lava, which are widespread between Lewiston, Idaho and Portland, Oregon as well as from Wenatchee, Washington to Walla Walla, Washington. Individual flow units exceed 100 meters in thickness and 1,000 cubic kilometers in volume. Some traveled many hundreds of kilometers from their vents (Reidel and others 1989). Erosion of these basalts by Pleistocene floods produced many of the cliffs found within the Columbia Gorge, Dry Falls, and the Channeled Scablands.

Volcanism began about 16 million years ago in eastern Oregon and northern Nevada (Pierce and Morgan 1992) and has shifted systematically northeast at about 3 centimeters/year to its present location in the Yellowstone area. This hot spot has been a major source of silicic volcanic rocks and is responsible for much of the present topography in the Snake River plain (ERUs 10 and 12) (Pierce and Morgan 1992). The topographic depression of the eastern Snake River plain is supported by silicic calderas that are covered by basalt flows. The largest known caldera eruption in or near the Basin occurred about 2 million years ago in the Yellowstone area (Christiansen 1979). About 620,000 years ago, eruption of approximately 1,000 cubic kilometers of tephra led to collapse of the Yellowstone caldera (Christiansen 1979). This eruption deposited volcanic ash over much of the present-day United States and Canada. The basalt flows of the eastern Snake River Plain represent the youngest volcanic activity following passage of the Yellowstone hot spot (that is, a few thousand years ago).

Earthquake hazards—Earthquake hazard risk is not uniformly distributed within the Basin. The map presented by Algermissen and others (1990) displays the maximum potential horizontal acceleration due to an earthquake not likely to be exceeded in 50 years. This map provides a reasonable regional assessment of earthquake hazard risk. Although urbanized areas west of the Basin have the highest probability for occurrence of substantial earthquakes, other parts of the Basin have experienced substantial earthquakes in recent times. In 1872, an earthquake of estimated Richter magnitude 7.4 occurred near Lake Chelan in Washington (Yelin and others 1994). In Montana, the Hebgen Lake earthquake of 1959 (Richter magnitude 7.3) produced fault scarps as high as 3 meters and triggered a landslide that dammed the flow of the Madison River, creating Quake Lake. The Borah Peak earthquake of 1983 (Richter magnitude 7.0) in Idaho produced a 36-kilometer long fault scarp along which the Lost River Range was uplifted between 1 and 2 meters (Stein and Barrientos 1985). Southeastern Idaho, the Yellowstone Park area, and the overthrust belt of Montana (parts of ERUs 7, 9, and 11-13) are also subject to earthquake risk (Algermissen and others 1990).

The effects of major earthquakes on human populations and social infrastructures are beyond the scope of this discussion. Less obvious is the likelihood for substantial change in aquatic ecosystems due to landslides caused by earthquakes. Despite the fact that earthquakes cannot be accurately predicted, the probability for future earthquakes in parts of the Basin are high.

Pleistocene Epoch Glacial and Flood Processes

At the watershed scale, much of the present landscape of the Basin was shaped by processes and events during the Pleistocene epoch (1.6 million years to 10,000 years ago). The Pleistocene epoch was a time of multiple cycles of major climate variation, ranging from ice ages to warm interglacial periods. The climax of the last cold period was 20,000 to 14,000 years ago when average summer temperatures in the Pacific Northwest were 5° to 7° C cooler and winter temperatures were about 10° to 15° C less than today (Barry 1983). During these cooler and moister times, large ice sheets formed in the northern hemisphere and covered most of Canada and the northern tier states of the United States (map 2.25) (Mickelson and others 1983, Waitt and Thorson 1983). The Pleistocene lobes of the ice sheet originating in Canada advanced into and retreated several times from the United States and excavated and molded valleys in ERUs 1 and 7 (Waitt and Thorson 1983).

Alpine glaciers shaped valleys along the entire east flank of the Cascade Range, the Klamath Mountains, the central Idaho Mountains, the mountains of western Montana, the Blue Mountains, Steens Mountain, and in the Yellowstone area of the Snake River headwaters (Porter and others 1983). Much of these glaciated landscapes are now covered with a mantle of glacial till. Downstream of glacier termini (and in the wake of retreating glacier termini), thick sedimentary sequences of silt, sand, and gravel outwash were left as valley fill and terraces that now flank most rivers with glaciated headwaters. Valley bottoms that were inundated by glacier-dammed lakes, such as much of the Clark Fork River drainage (ERUs 8 and 9) and the Columbia River upstream of Grand Coulee (ERUs 5 and 7), as well as pluvial lakes developed in closed basins (ERUs 4,10, and 11) during wet periods, now have thick mantles of fine-grain lacustrine deposits (Benson and Thompson 1987).

During the Pleistocene ice ages, silt and fine-sand outwash from alpine and continental glaciers and glacial floods were redeposited by wind as thick blankets of loess. These loess deposits locally dominate many of the landscapes of the Basin. For example, the rolling hills of the Palouse in eastern Washington are entirely composed of loess that has been deposited over the last 2 million years and is

Map 2.25—Regional map showing aspects of the late Pleistocene paleogeography of the Pacific Northwest.

locally over 75 meters thick (Busacca 1991, Busacca and McDonald 1994). Sequences of loess mantle much of the Columbia Plateau (ERU 5) and Snake River plain (ERUs 10 and 11) (Malde 1991). These loess deposits are highly productive, and most agriculture in these ERUs are dependent on soils developed from loess.

The wetter climate of the last ice age led to the formation and expansion of large freshwater lakes in closed basins throughout the western United States (Benson and Thompson 1987). The presence of these lakes resulted in deposition of silt and clay on inundated valley floors and substantially altered the patterns of hydrologic connectivity between now-separated basins. This situation strongly affected the distribution of many aquatic species within the Basin. In the Basin and Range province of Oregon, there were nine major pluvial lakes, the largest of which was pluvial Lake Modoc that covered 2,800 square kilometers and included Upper and Lower Klamath lakes. Additionally, Summer Lake and Lake Abert were connected into the 1,200-square-kilometer, pluvial Chewaucan Lake. Goose Lake expanded and fully integrated into the Sacramento River system. In a similar manner, the Warner Lakes are remnants of pluvial Coleman Lake, the Harney-Malheur Lakes are the remnant of pluvial Malheur Lake, and Alvord Lake (in the Alvord Desert) is a remnant of pluvial Lake Alvord (Allison 1982, Orr and others 1994). Each of these pluvial lakes covered about 1,300 square kilometers at their maximum extent, between 15,000 and 13,500 years ago (Benson and others 1990). All of these lake systems rapidly evaporated at the end of the Pleistocene, and by 10,000 years ago, most lakes approximated their present size.

During the last ice age, the drainage systems of Big Lost River, Little Lost River, Birch Creek, Medicine Lodge Creek, Beaver Creek, and Camas Creek (which are all now influent into the basalts that underlie the Snake River Plain) combined to form pluvial Lake Terreton, a large shallow lake on the Snake River Plain (Pierce and Scott 1982). Between 14,500 and 13,000 years ago, an even more profound drainage integration occurred when much of the eastern Great Basin was temporarily connected to the Columbia River drainage as a result of pluvial Lake Bonneville overtopping its lowest divide between the closed Bonneville basin and the Portneuf River drainage in southeastern Idaho (Gilbert 1980, O'Conner 1993). Rapid breaching of ice-dammed lakes and the pluvial Lake Bonneville spillover led to cataclysmic flooding that dramatically affected the physiography of the Columbia Plateau and Snake River Plain.

The Bonneville Flood resulted from the filling and consequent spillover of Pleistocene Lake Bonneville into the Snake River drainage about 14,500 years ago. About 4,750 cubic kilometers of water was released from this flood within a period of a few weeks near Red Rock Pass, Idaho and traveled down the present courses of Marsh Creek and the lower Portneuf River before entering the Snake River Plain north of Pocatello. For the most part, this flood route followed the present course of the Snake River, locally widening and deepening the canyon. Some of the large falls, such as Shoshone and Twin Falls (anadromous fish blockages), are parts of large cataract complexes that formed during the flood. The Bonneville Flood substantially modified the valley of the Snake River as far downstream as Lewiston, Idaho. Downstream of Lewiston, Bonneville Flood features are buried by subsequent Missoula Flood deposits (Malde 1968, O'Conner 1993).

Between 15,000 and 12,000 years ago, a lobe of the Cordilleran Ice Sheet advanced down the Purcell Trench and blocked the Clark Fork River near the present site of Lake Pend Oreille. At its maximum extent, the resulting glacial Lake Missoula inundated as much as 10,000 square kilometers with 2,500 cubic kilometers of water (Craig 1987). Repeated formation and failure of the ice dam led to flooding that overwhelmed normal drainage routes in northern Idaho and eastern Washington. As the Missoula floods spread

through eastern Washington, they carved the "channeled scabland" by stripping loess off basalt surfaces and eroding river courses and large falls and depositing immense gravel bars (map 2.25).

Dry Falls in central Washington, now abandoned by the Columbia River, was the site of an immense waterfall created by Lake Missoula flooding. Falls created by eroded basalts on the Spokane and the Palouse Rivers from this flooding created fish migration blockages. Tributary valleys such as the Snake, Yakima, Walla Walla, Tucannon, John Day, Klickitat, and Hood Rivers (ERU 5) were mantled by sand and silt carried by floodwater backed-up into these side valleys. Large basins such as the Quincy, Pasco, and Umatilla Basins were filled with immense volumes of sand and gravel. There were as many as 100 Lake Missoula flood events between 15,000 and 12,000 years ago as the ice dam repeatedly formed and failed (Atwater 1986, Baker 1983, Baker and Bunker 1985, Bretz 1923, Waitt 1980, Waitt 1985).

Minerals and Mining Impacts

Mineral resource needs have contributed to the exploration and development of metallic and industrial minerals within the Basin. Important metallic and industrial mineral resources within the Basin include gold, silver, lead, zinc, molybdenum, copper, sand, gravel, and stone. Even though there are thousands of mineral deposits, prospects, and occurrences in the Basin, a small number of world-class deposits account for most of the production and resource base. (Refer to the Economic Assessment for a discussion of mineral development in the Basin.)

Mineral deposits are not distributed uniformly through the Basin and tend to occur in clusters or belts, which ultimately reflect the underlying geological processes that control their distribution. The locations of substantial metallic deposits and mines (defined as having past production and/or known reserves of greater than a threshold value) within the Basin and adjacent regions have been described by Bookstrom and others (in press b).

The USBM estimated that there are nearly 14,000 inactive or abandoned mining sites in the Basin. Although environmental effects from mining may be substantial, they tend to be restricted in areal extent. Mining activities have also resulted in locally important landscape, aquatic, atmospheric, and visual disturbances.

In undisturbed areas, aquatic and terrestrial ecosystems have adapted to the fluxes of metal and mineral deposits exposed at the earth's surface. Mining, however, can expose large volumes of rock to physical and chemical weathering, which may increase the rates of introduced metals, acid drainage, or sediment to the environment if unmitigated.

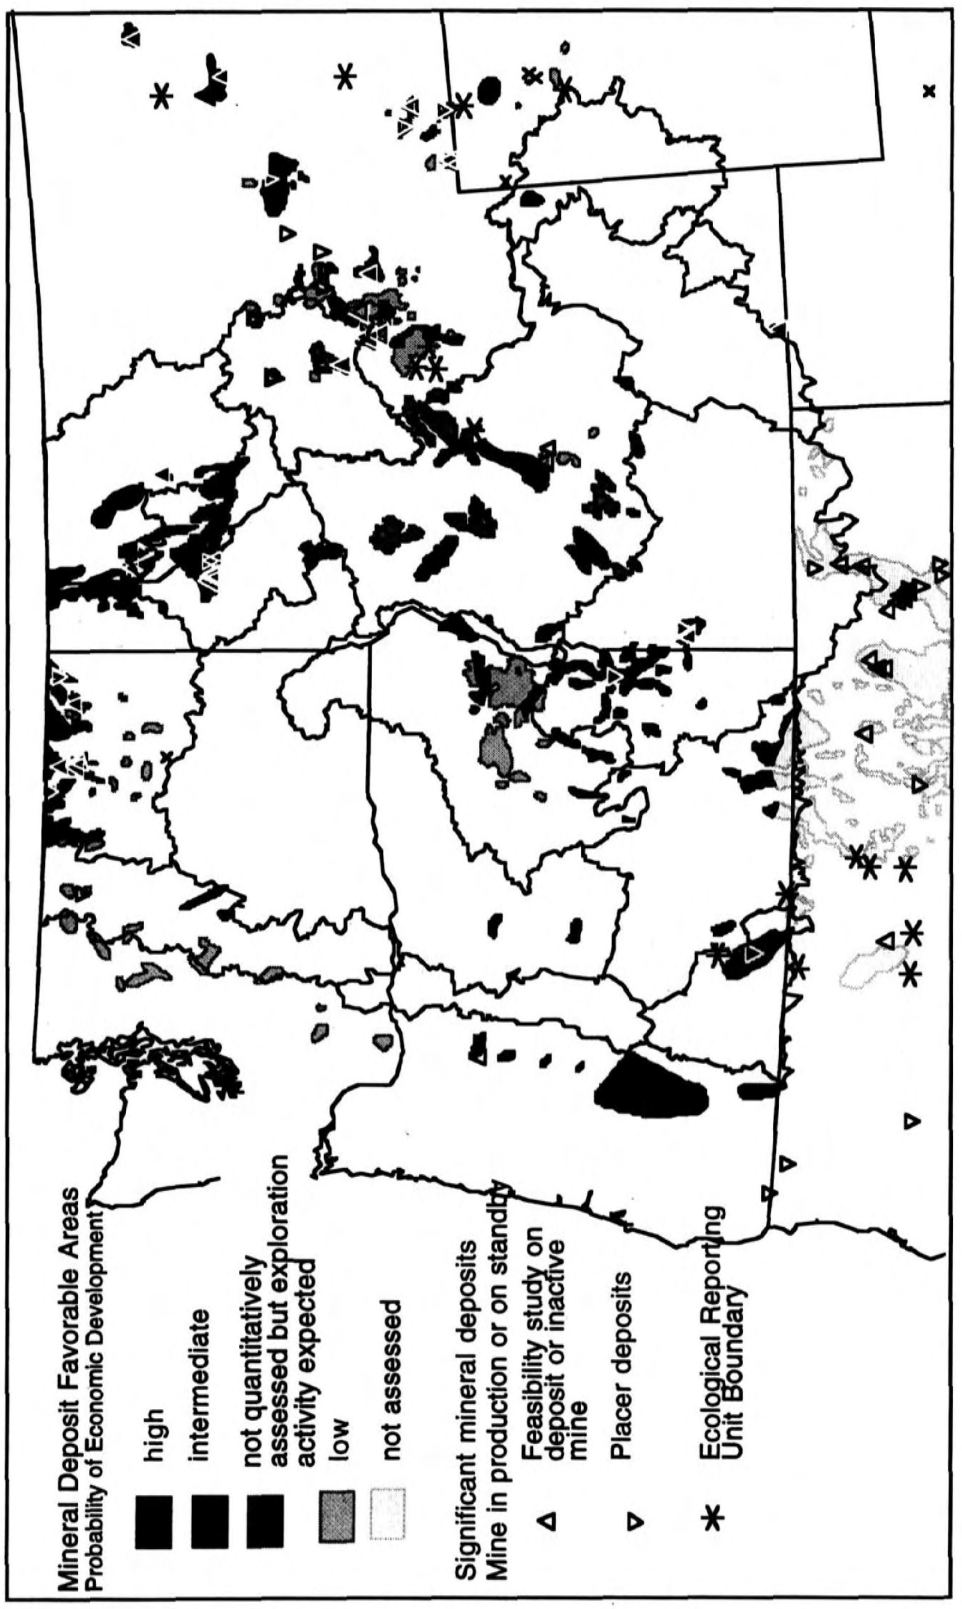
Past mining activities within the Basin have had profound effects on some aquatic and riparian ecosystems. The Clark Fork River in Montana, for example, has four distinct but contiguous Environmental Protection Agency (EPA) Superfund National Priority List sites covering 8,100 hectares along 235 kilometers of river. As a result of mining discharges at the Clark Fork River's headwaters near Butte and Anaconda, Montana, this river is considered to be of concern for metal exceedences under section 303(d) of the Clean Water Act for 200 kilometers downstream to where it is joined by the Flathead River (EPA 1980). The South Fork of the Coeur d'Alene River basin in Idaho is host to a world-class lead-zinc-silver mining district. Mining began in this area in the 1800s; from that time to as recently as 1968 spent tailings from some mills were discharged directly into the river (Horowitz and others 1993). Mining of placer deposits has also locally modified aquatic habitat in parts of the Basin. The extraction of most resources, including gold and industrial minerals, was processed by gravitational separation from the waste rock, although mercury was used to amalgamate gold in some historical placers. Most placer mining has been for gold, although there are numerous garnet sand placers in parts of ERUs 5, 7, and 8. Exploitation of sand and gravel resources has also locally modified aquatic condition in some drainages.

In addition to potential increases in the release of metals such as zinc, lead, cobalt, copper, arsenic, or other metals, some mineral deposit types are more prone to produce acid rock drainage than others (Plumlee and others 1994). Deposit types high in pyrite and other acid-producing sulfide minerals and low in acid-buffering minerals such as calcite, aragonite, or dolomite have a high potential for producing acid rock drainage (Kwong 1993, Plumlee and others 1994). When mined and exposed to air and water, weathering of naturally acid-producing minerals is accelerated and appropriate remediation technologies must be employed to prevent acid-rock drainage problems. Acid-rock drainage for a given deposit type will also have a greater or lesser probability, depending on the amount of water available, to react with the contained minerals.

The USGS has classified the areas that are favorable for mineral development according to their risk of acid rock drainage if remediation technologies are not employed (Zientek and others, in press b). In this classification, areas are subdivided (Kwong 1993; Plumlee and others 1994; Zientek and others, in press b) into three groups:

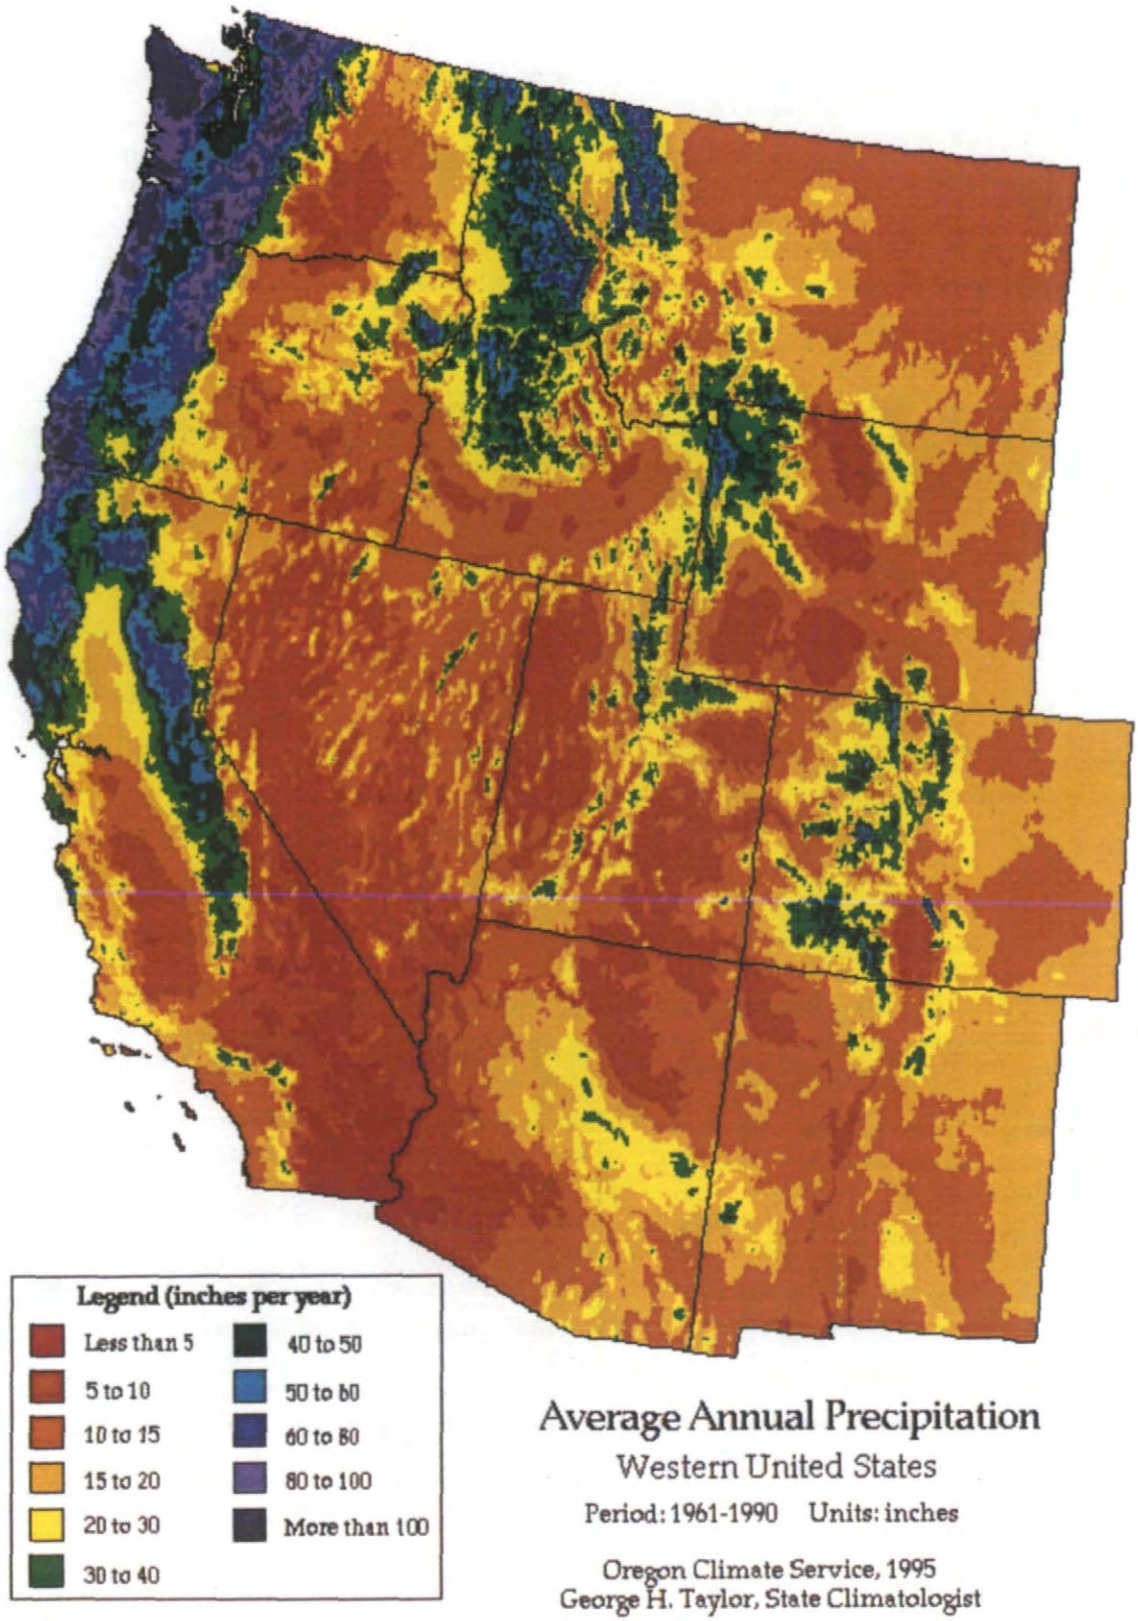
- Those deposit types with a high risk of generating acid rock drainage (that is, they have a high sulfide mineral content and a low buffering capacity of the characteristic host and alteration mineralogies).
- Those that may generate acid rock drainage depending on local climatic, hydrologic, and site-specific deposit characteristics.
- Those that have low potential for acid rock drainage due to low sulfide mineral content and/or high buffering capacity of the characteristic mineralogies.

Potential impacts from unmitigated resource extraction and processing of ores include release of metals, acid-rock drainage, atmospheric emissions, and increased sediment loads to the environment. Map 2.26 shows a compilation of the areas favorable for metallic mineral deposit types in the Basin, ranked according to the worst-case inherent potential for deposits in those areas to generate acid rock drainage (Zientek and others, in press b). Individual site characteristics must be evaluated before a given prospect or deposit can be classified as having high, moderate, or low potential for generating acid rock drainage.



Climate Features

The Basin is in a transition-type climate zone. It is influenced by three distinct air masses:



- Moist, marine air from the west that moderates seasonal temperatures.
- Continental air from the east and south, which is dry and cold in winter and hot with convective precipitation and lightning in summer.
- Dry, arctic air from the north that brings cold air to the Basin in winter and helps cool the Basin in summer.

These air mass types interact with each other in a region of complex topography. Most precipitation accumulates during winter (75 to 125 cm in the Eastern Cascades, 25 to 95 cm in the Northern Rockies, and 20 to 40 cm in the Central Columbia and Snake River Plateaus)(map 2.27). The mountain snowpack acts like a natural reservoir and supplies the Basin with most of its useable water. Only the eastern and southern parts of the Basin have summer maximum precipitation, which is associated with significant thunderstorm activity. Summer precipitation throughout the Basin ranges from about 20 to 50 centimeters. Since the 1970s, winter precipitation generally has decreased to a level comparable to the 100-year historical mean. Summer precipitation has increased during the last 30 years, similar to 1910 values.

Temperatures are generally mild in the Basin because of periodic influxes of moderating Pacific moisture. Winter mean monthly temperatures

Map 2.26—Map showing mineral deposit favorable areas ranked by anticipated levels of economic activity.

Map 2.27—Average annual precipitation (western United States).

range from minus 10° to minus 3° C while summer temperatures range from 10° to 15° C. Trends in the last 100 years indicate a slight increase in temperatures during all seasons.

The timing and extent of competing air masses is controlled largely by synoptic weather patterns and local terrain features that vary across the Basin. Prolonged periods of drought occur when Pacific storms are deflected around the region, preventing the intrusion of moist, marine air. At these times dry, continental conditions prevail. Damaging frosts and freezing conditions commonly occur when Arctic air invades the Basin before winter hardening in autumn or after budbreak in spring. Cold damage also may occur in winter if a warm, marine intrusion is followed by a sweep of Arctic air. In addition, the unique interplay between air mass types results in dramatic changes during transition. The most unique of these transitions is rain-on-snow flooding that occurs when warm, wet marine air displaces cold, Arctic conditions in winter. Lightning and gusty winds also occur during transitions between continental and marine air masses, mainly in spring and summer.

An interesting analysis of temperature found two major frontal zones in the Basin (Mitchell 1976). A Pacific air mass boundary, which dominates during summer, extends diagonally across the Basin from northwest California to northwestern Montana. Relatively moist, marine air exists north of the boundary and drier, continental air is common south of the boundary. Mitchell noted that the Pacific boundary coincides with the eastward extension of coastal vegetation found in northern Idaho and northwestern Montana. A westerlies-anticyclone boundary, which dominates during the winter, was found to stretch east-west along the Oregon-Nevada border and across northern Utah. It marks the boundary between a region of prevailing westerly winds in the north and southerly winds in the south, caused by circulation around a persistent center of high pressure (anticyclone) over southern Nevada. This frontal zone also coincides with the northern or southern extent of several tree species.

Bryson and Hare (1974) and Mock (1996) have found that while large-scale climate controls (such as the polar jet stream, Pacific subtropical high, and subtropical ridge) play important roles in precipitation variability, small-scale climate controls (such as the complex topography, thermal troughs, confined mixing heights, and convective systems) can dominate.

Weather Data

Recorded weather observations began in the western United States during the late 1800s. Because population was relatively sparse at that time, only eight stations within the Basin have continuous, quality-controlled records approaching 100 years. These are Spokane WSO, Washington; Dufur, Oregon; Fortine, Kalispell WSO, and Haugan, Montana; and Priest River Experiment Station, Caldwell, and Saint Ignatius in Idaho.

High quality measurements of temperature, dew point, relative humidity, wind, precipitation, and radiation data are collected from the National Weather Service first-order stations that are operated by trained observers. Another source of daily precipitation and temperature measurements is maintained by the National Weather Service, Cooperative Observer Network (COOP)(National Climatic Data Center 1991). Data from COOP stations provide the highest spatial resolution of daily measurements although consistency and quality can be somewhat lacking. Observation sites for these two types of stations are usually located near population centers or airports away from the wildland areas of forests and mountains.

Significant additions to high elevation data occurred in the mid-1930s as snow course observations increased and in the late 1970s with the installation of SNOTEL sites and remote automated weather systems (RAWS). Snow course and SNOTEL sites are commonly placed near the headwaters of major river basins. Snow water equivalent measurements are available from both

types of stations. SNOTEL sites additionally transmit precipitation and temperature. RAWS stations are designed to support fire weather forecasting so they operate mainly during summer and are located in forest clearings on hill slopes and ridges. RAWS stations transmit hourly information on air temperature, precipitation, fuel temperature, relative humidity, and wind. There are about 200 RAWS, 200 SNOTEL, and 200 snow course sites in the Interior Columbia River Basin.

A northwest cooperative agricultural weather network (AgriMet) is maintained by the Bureau of Reclamation in Boise, Idaho as part of the Pacific Northwest Hydrometeorological Network for river and reservoir management.[1] Historical data since 1983 include daily soil moisture, soil and air temperatures, crop water use, and evapotranspiration.

A consistent network of radiosonde observations (RAOBs) began in the mid-1930s (U.S. Department of Commerce 1964). RAOB sensors measure wind, temperature, dew point, and height at mandatory atmospheric pressure levels (such as surface, 850 mb, 700 mb, 500 mb) and other significant levels twice a day. Stations at Spokane, Washington and Boise, Idaho are the only stations within the Basin that regularly report these data.

There are over 600 mountain weather and snowpack observations in the Basin, but the stations are spaced too far apart (50 to 150 km) to represent small-scale climate caused by complex topography in the region. Consequently, model-generated data play an increasing role in climate analyses of the mountainous west. Three sets of model-generated data were available for this study:

- Historical means of monthly and annual precipitation at 2.5-minute (about 5 km) and 5-minute (about 10 km) latitude/longitude spatial resolution from the PRISM model (Daly and others 1994).
- Daily temperature and precipitation for three characteristic years (1982, 1988, and 1989) at 2-kilometer resolution from the MTCLIM-3D model (Thornton and Running 1996).
- Monthly mean winds at 5-minute latitude/longitude resolution from the WINFLO model (Ferguson, in review).

Trends in Regional Climate Patterns

Prior to about 1900, climatic trends in the Basin could only be determined using proxy data such as that evident from tree rings, glacier fluctuations, ice cores, deep sea sediments, lake levels, and fossil pollens. Several major epochs in modern climate have been manifested globally (Intergovernmental Panel on Climate Change 1990). (Moderate climate is considered by many to have begun after the last major ice age, about 10,000 years ago.) A thermal maximum occurred between about 9,000 and 5,000 years ago (Holocene period) when temperatures were 1° to 2° C greater than today. Another warm period occurred between A.D. 1000 and 1250, known as the Medieval Climatic Optimum, with temperatures about 0.5° C warmer than today. A "Little Ice Age" between A.D. 1550 and 1850 caused low snow levels and advancing mountain glaciers.

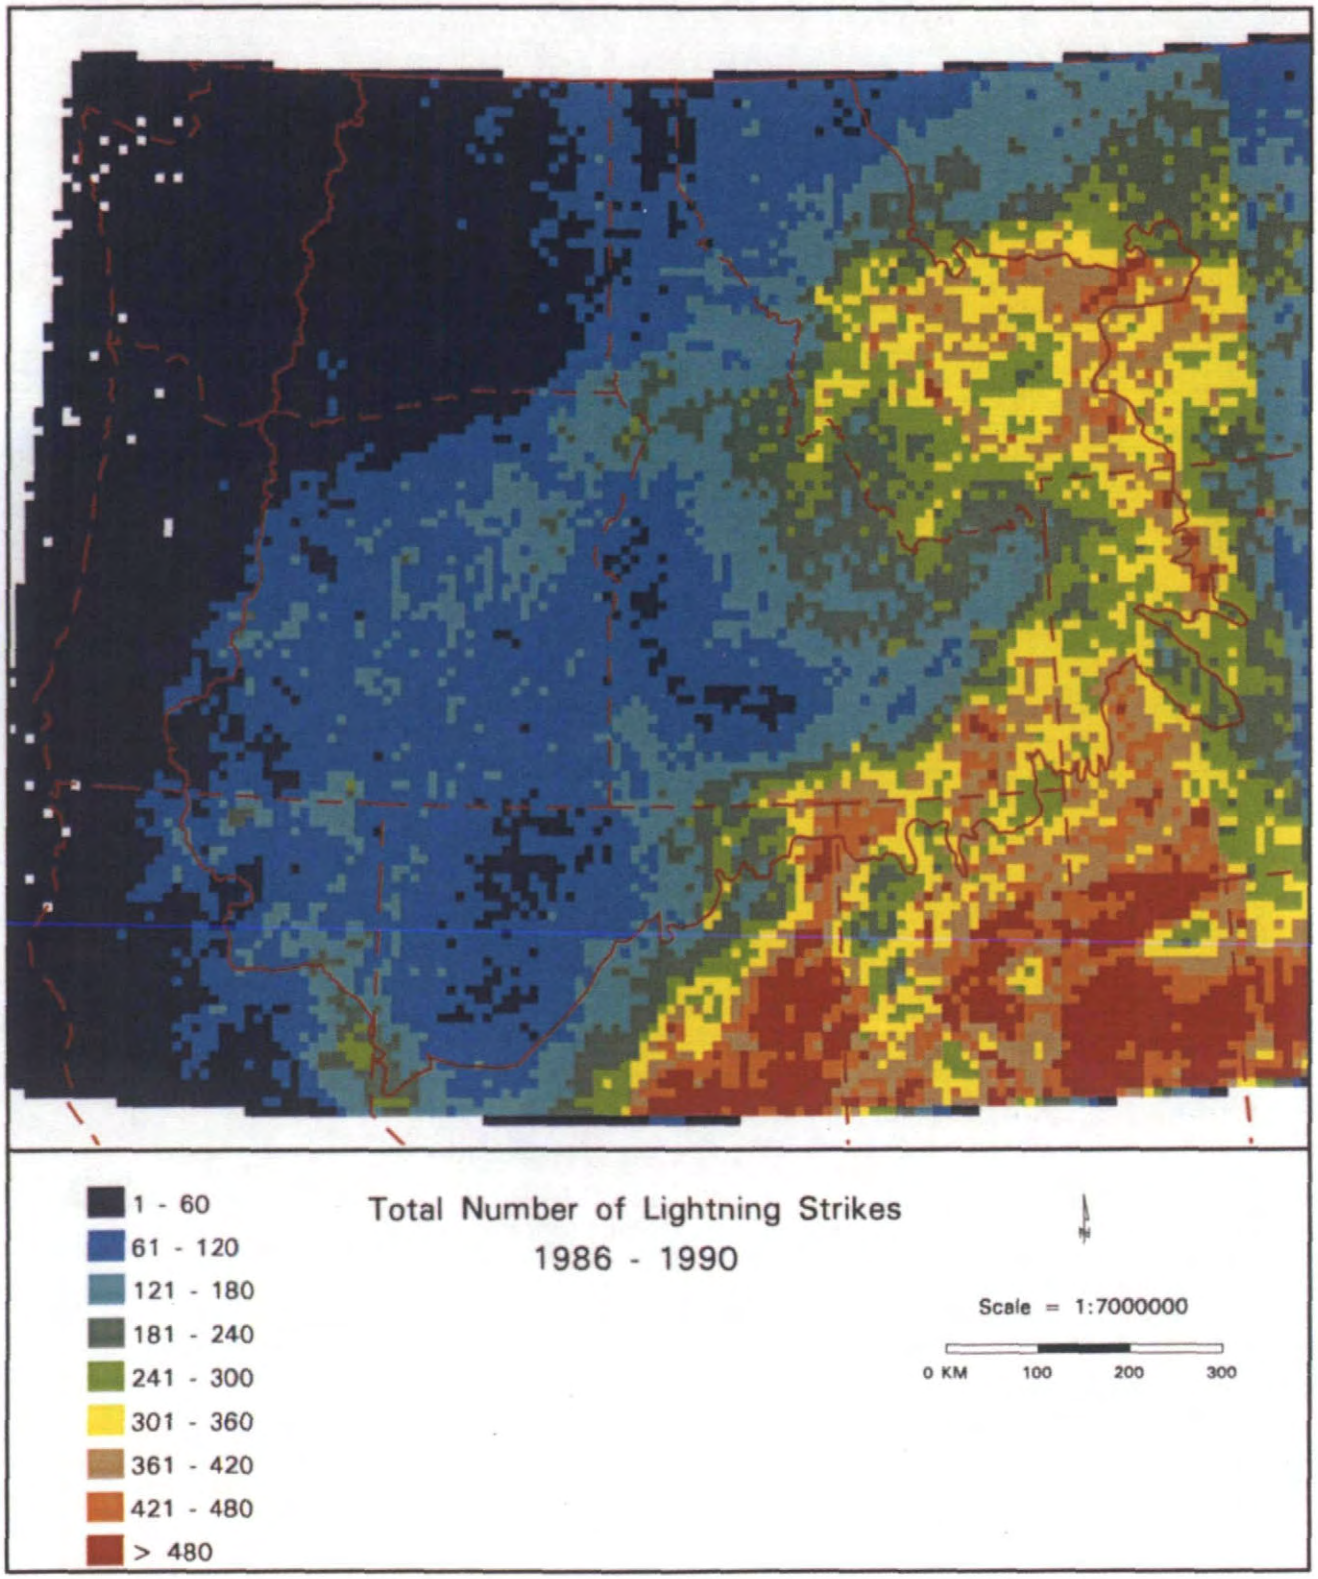
Regional trends in ancient climate also are noteworthy. For example, fossil-pollen data show variable responses to alternating warm, dry and warm, wet climates in the Holocene period (NOAA 1992 and 1993; Whitlock and Bartlein 1993) with the spatial heterogeneity controlled primarily by topography (Davis and others 1986; Whitlock and Bartlein 1993). In more recent times, local tree-ring chronologies (for example, Briffa and others 1992) suggest periodic warm periods in 1630s, between 1640 to 1660, 1790s, and the 1920s, with temperatures about 0.5° C greater than the 1881 to 1982 average. Alternating cold periods also are apparent in the chronologies, with the most significant from 1870 to 1900 (about the time of the Little Ice Age) having

temperatures 0.2° to 0.5° C less than the 1881 to 1982 average.

Historical weather observations within the Basin began in the late 1800s around the time that the Little Ice Age ended. Since then, mountain glaciers have generally retreated (Ferguson 1992, Meier 1984), which is a sign of general warming. Drought occurred in the 1930s, 1950s, and 1980s. There appear to be decadal trends in regional climate that could be related to the El Niño Southern Oscillation (ENSO) and Pacific North American (PNA) indices (Cayan and Peterson 1989, Redmond and Koch 1991, Ropelewski and Halpert 1986, Yarnal and Diaz 1986). These trends are most obvious in streamflow fluctuations, which aggregate precipitation and temperature signals over large areas of the catchment and drainage basin of the stream.

Disturbance Climate Events

Climate patterns that disrupt ecosystem processes are common and often critical components in the natural cycle of events. Although the Basin is not known for extreme climate events, many climatic features that are ordinary to the Basin (such as summer cold fronts fanning wildfires or rain-on-snow floods) cause significant disruption of ecosystem processes.



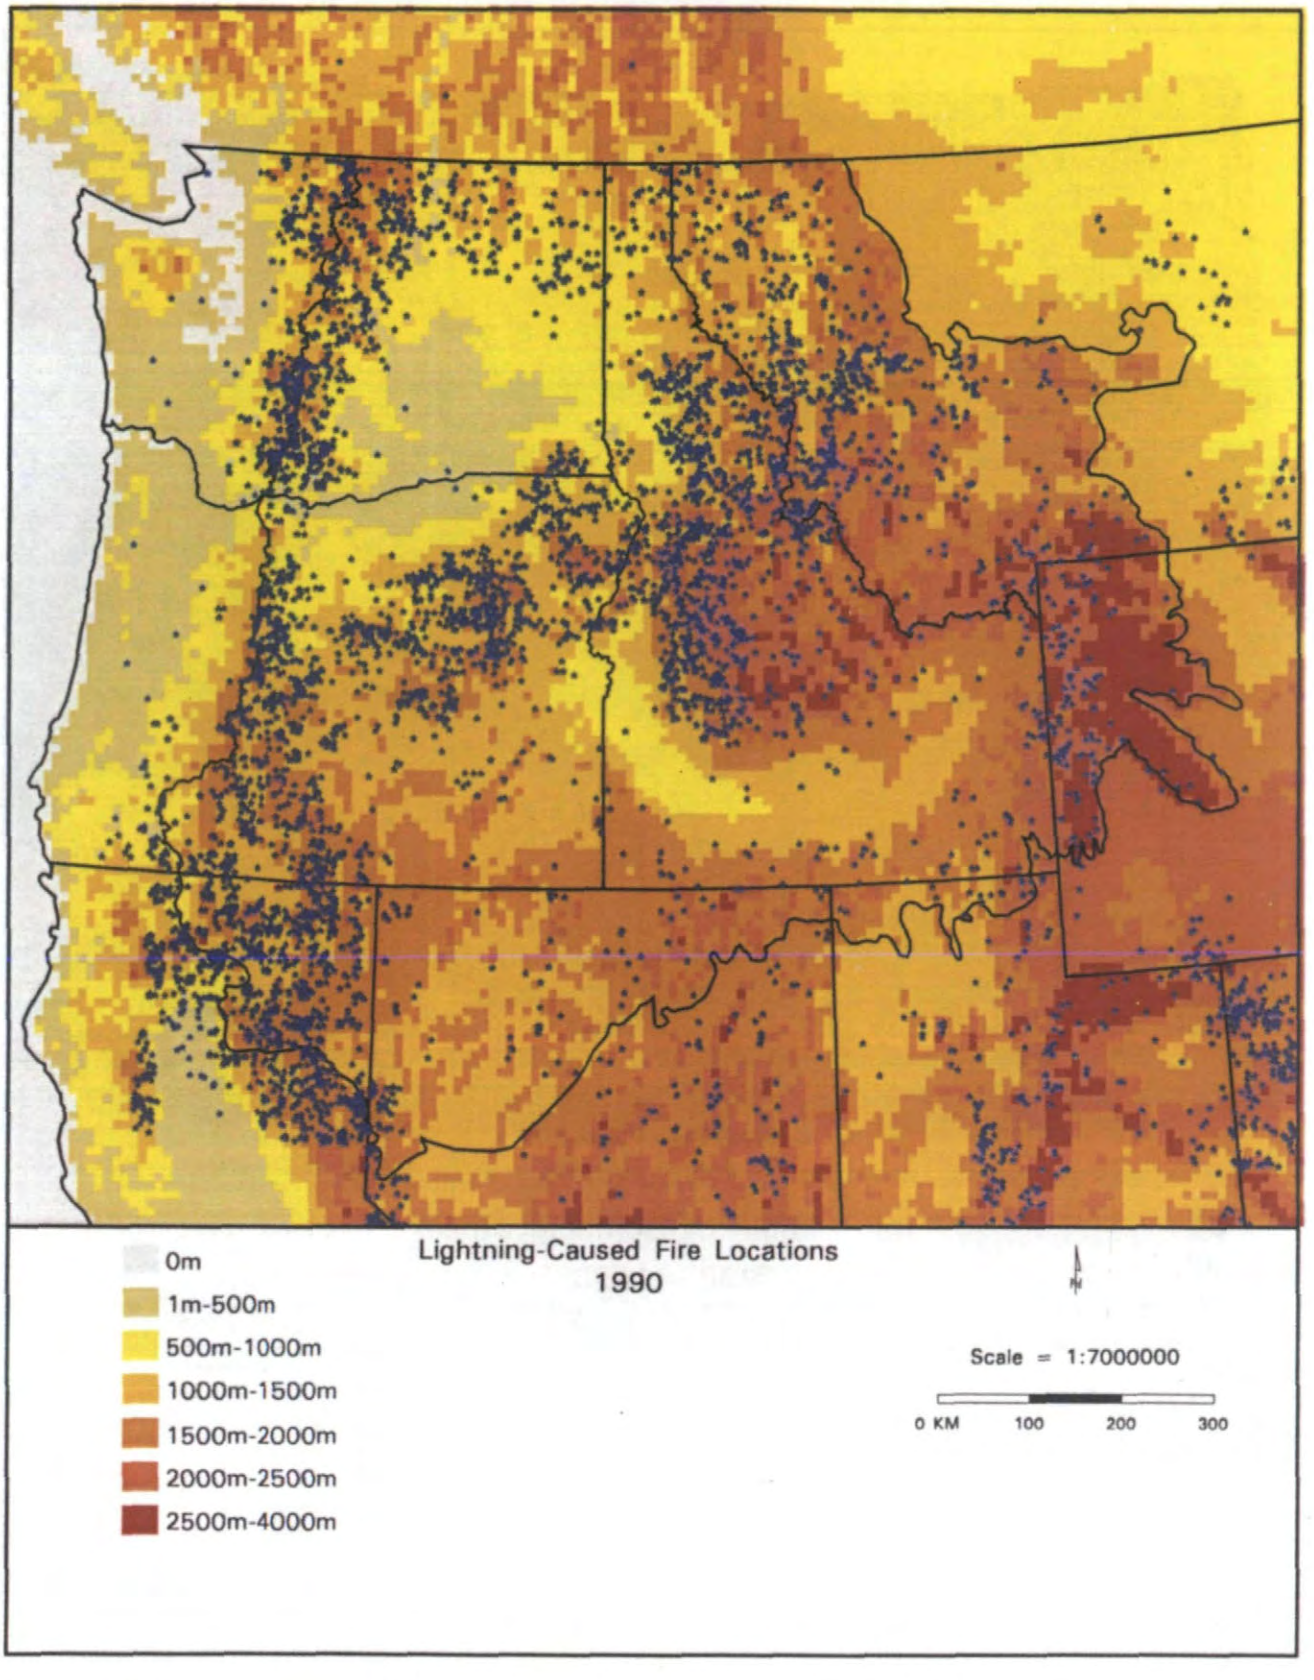
Lightning—Cloud-to-ground lightning strikes are the most common cause of wildfires in the western United States. Although the number of lightning strikes in the Pacific Northwest is low compared to elsewhere in the Nation (Orville 1994), their fire ignition potential is no less significant.

Until 1983, the best lightning occurrence data were available from fire lookouts. The data from more that 2,600 storms that were observed from 404 fire lookouts in Washington and Oregon from 1925 to 1931 were analyzed in a classic study by Morris (1934). He found that most lightning storms occurred on the south side of the Blue Mountains in eastern Oregon and in the Colville district of northeast Washington. Smaller areas of high frequency lightning occurred on the east slopes of the Cascade mountains in the Okanogan and Deschutes forest districts.

With the advent of an automated lightning detection system (Krider and others 1980, Latham 1983, Rasch and Mathewson 1984), more detailed and ongoing analysis of lightning strike frequency patterns became possible. Hill and others (1987) analyzed lightning frequency pattern in Idaho with automated lightning data from 1985 and 1986. The greatest number of strikes were found to occur in Idaho's southeast corner.

A summary of lightning frequency during the period 1986 to 1990 (map 2.28) shows that the highest lightning frequencies occur near the perimeter and outside the boundary of the Basin, in the higher elevations of Nevada, Utah, Wyoming, and Montana. Within the Basin, highest frequencies are observed in western Montana, the Idaho panhandle, and eastern Oregon. Very few lightning strikes were recorded throughout the period of record in most of Washington and the western half of Oregon, except a relatively high number of strikes occurred in the Oregon Cascades in 1989 and 1990. It is important to note that higher frequencies observed in regions where lightning is typically rare are likely the result of one or two individual storms, rather than a higher occurrence of lightning throughout the course of the year. Also, detectors only record about 70 percent of total strikes (Orville 1994) so numbers of strikes should be viewed in relative terms instead of exact magnitudes.

The number of lightning strikes in a given area does not directly correspond to the number of wildfires. Most lightning-caused fires in the Basin occur in the Blue Mountains of northeast Oregon and Sawtooth-Bitterroot ranges of central Idaho and far-western Montana (map 2.29), whereas most lightning strikes occur in southern Idaho and the Montana Rockies. This is somewhat contrary to the 1934 work of Morris, who found that lightning-caused fire locations agreed relatively well with lightning storm locations reported for the same period in Washington and Oregon.



Map 2.28—Total number of lightning strikes (1986-1990).

Map 2.29—Lightning-caused fire locations (1990).

Morris noted, however, that some storms ignited many more fires than others. Certainly fuel condition plays a significant role in flammability. Efforts to distinguish between dry lightning, which occurs with little or no precipiation, and wet lightning, with accompanying precipitation, show promise for determining lightning ignition potential (Peterson and others, in preparation).

Frontal passage and the spread of wildfire—Weather fronts often are associated with strong, gusty winds. This especially is true of cold fronts. During typical years (as in 1989), five to seven significant frontal events are possible during the fire season. In cool wet years (as in 1982), only two to four cold fronts appear to pass over the area.

In warm dry years (such as the 1988 fire season), 8 to 20 gusty wind events can occur. During these seasons, the continental air mass heats and dries out. The cool moist air masses from Pacific storms that progress eastward are dramatically different from the hot, dry continental air masses. As the air masses meet, associated fronts can be very strong. This effect is most significant when the seasonal upper-level flow pattern includes frequent meridional, or northerly flow, over the Basin. During the 1988 fire season, the most severe of the century, it was observed that the frequency of dry cold fronts passing over the northern Rockies in August and early September caused ongoing wildfires to make major runs (National Weather Service 1988).

Blow-down—Strong winds that cause forest damage are common in the Pacific Northwest. For example, around the outflow of the Columbia Gorge and Snake River plain, sustained wind speeds of 20 meters per second (about 45 mph) have two-year return intervals, and gusts with higher speeds are even more prevalent (Wantz and Sinclair 1981). In addition, many steep-walled valleys and canyons can channel and accelerate winds to damaging speeds.

Significantly strong winds and storm winds that occur in other than prevailing directions are the dominant climate components to blow-down potential (Boose and others, in review). Trees most susceptible to blow-down usually are exposed to recently created up-wind fetches like the edge of clearcuts made while harvesting timber or for agriculture and land development. Stand structure, tree health, soil stability, and accumulation of snow and ice can aid in blow-down potential (Lohmander and Helles 1987; Miller and others 1987; Schaetzl and others 1988).[2]

Trees at all elevations in the Cascade passes can become wind-hardened to the prevailing westerlies. During winter, the offshore flow is channeled through the Cascade passes and strong easterly winds result. Because the east winds are stronger and completely opposite to the wind-hardening westerly direction, blow-down is common in the passes during winter. Elsewhere around the Basin, trees at high elevation are wind-hardened to prevailing southwesterly upper-level flow patterns; trees at lower elevation usually are less wind-hardened.

A gap flow similar to that in the Cascade passes may play an important role for blow-down potential in northeastern Washington and northern Idaho. Here, deep river valleys funnel and help accelerate pressure gradient winds through the forests. The direction of these gap winds depends on whether storms pass over north or south of the area. Because trees are wind-hardened with dominating downslope flow in summer, the strength and direction of gap winds in the Colville, Okanogan, and Panhandle forests are significant enough to cause blow-down.

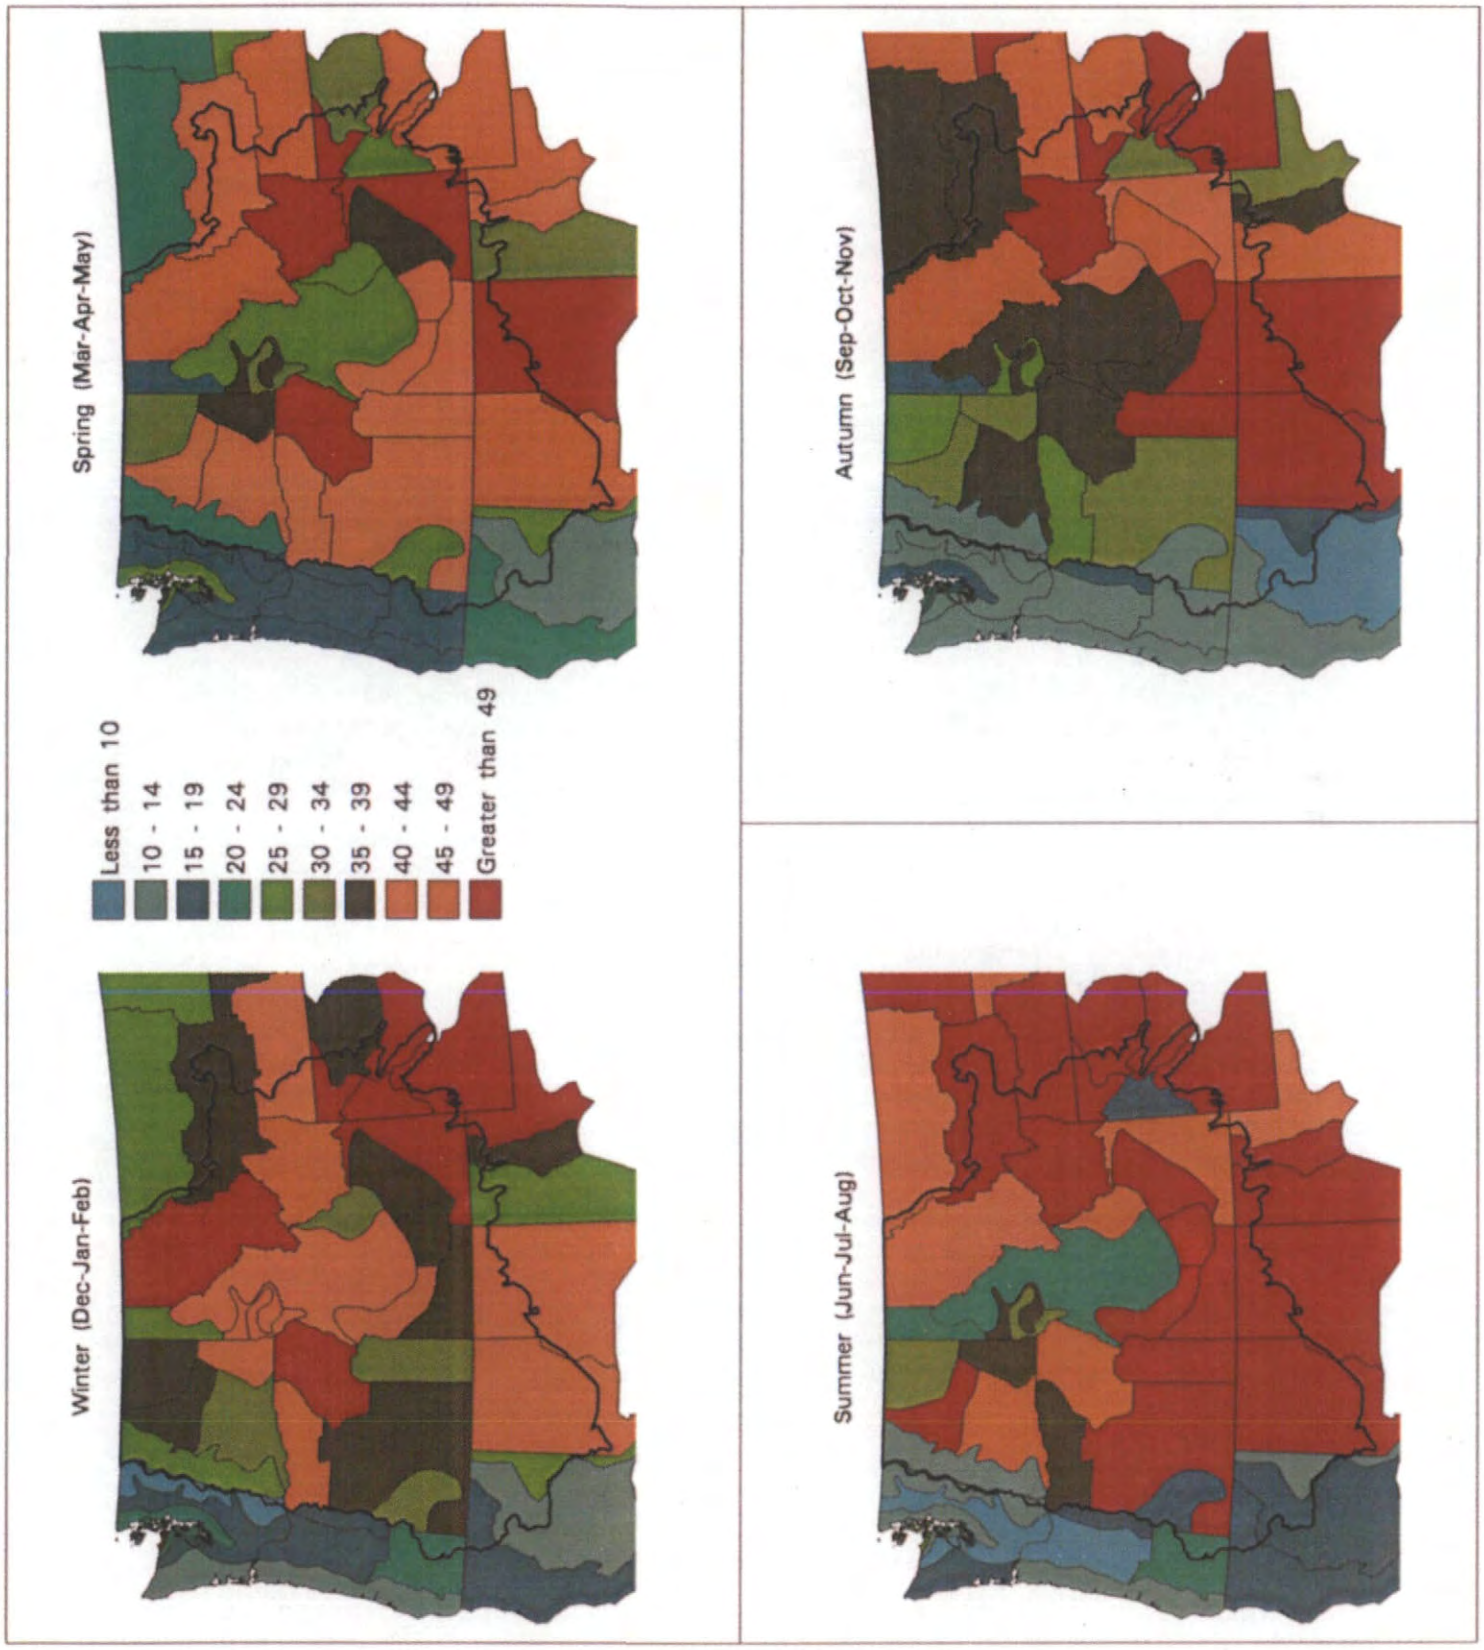
Strong winds in the upper Snake River plain result from converging air as the valley turns and narrows. The combination of high mountains and steep valleys contributes to strong wind patterns in far western Montana.

Drought—Drought in the Columbia River Basin is common, but is tempered by an abundant source of moisture that spills over the Cascade

[2] Also personal communication. 1996. Diana Sinton. Ph.D. candidate, Department of Geosciences, Wilkinson Hall 104, Oregon State University, Corvallis, OR 97331.

Range and through mountain gaps from the Pacific Ocean. Most often, drought is limited to small areas of the Basin or short periods. Severe, multiple year, Basin-wide droughts occurred in the 1930s and late 1980s. Because most summer water resources rely on winter snowpack, severe droughts occur with abnormally low winter and spring snowfalls (Namias 1983), which are correlated to El Niño southern oscillation in streamflow runoff patterns (Cayan and Peterson 1989). For example, the 1977 and 1988 winter droughts were associated with El Niño events. El Niño patterns occur every one to seven years (Philander 1983, Rasmusson and Wallace 1983). Therefore, it may be reasonable to expect that drought in the Basin would have a similar return interval.

To help determine the spatial pattern of drought events, Palmer Drought Severity Index (PDSI) data (Heddinghause and Sobol 1991, Palmer 1965) were obtained from the National Climate Data Center (NCDC). Drought frequency patterns from 1985 to 1994 were summarized for every season (map 2.30). During winter, drought is most common in places that typically have heavy winter precipitation, which is dependent on positioning of the jet stream and related storm tracks. During some years, the winter storm track remains west to northwesterly, and storms penetrating inland are too weak to maintain strength after crossing the coastal mountain barrier. This causes winter drought to be most frequent in areas that do not have enough topography to enhance lifting or convergence with weakened westerly winds: for example, on the east side of the Columbia Gorge (the coastal barrier's most significant gap), the Blue Mountains (which rely on abundant moisture from the southwest), and some of the lower-elevation inland areas in Idaho, and western Montana and Wyoming.



In spring, convective precipitation becomes important. Because convection is highly variable year-to-year, those places that depend on convective precipitation have more frequent periods of drought. This includes most of the Basin, except for some of the mountain areas near the Cascades, which benefit from spillover Pacific moisture, and places in northern Washington and Idaho, which collect moisture from a few storms that pass over Canada during summer. Winds at the head of the Snake River commonly converge, and this helps enhance lifting and precipitation to slightly reduce drought there.

During summer, the reliance on convective precipitation becomes even more apparent with a spatial pattern of drought similar to those of spring but with somewhat higher frequencies. In autumn, the winter storm tracks begin to establish, which helps to relieve much of the northwestern and mountainous parts of the Basin. The south and southeast portions, however, retain some reliance on the highly variable convective precipitation. Therefore, these regions of the Basin experience drought whenever autumn convection is minimal.

Cold damage potential—Very cold temperatures can damage vegetation and cause surface and ground water to freeze. Short-term freeze primarily affects new growth. Long-term freeze can affect lake and stream systems and cause sustained damage to mature vegetation.

Previously stressed trees are more likely to sustain damage from temperatures that normally cause no damage (Levitt 1980). Micro-scale topographic effects also are factors in cold damage. Trees on north- and west-facing slopes receive more damage during winter storms than those on south- and east-facing slopes (Porter 1959). On cold clear nights, saplings in hollows and valleys are much more prone to frost damage due to pooling of frigid air (Blennow 1992).

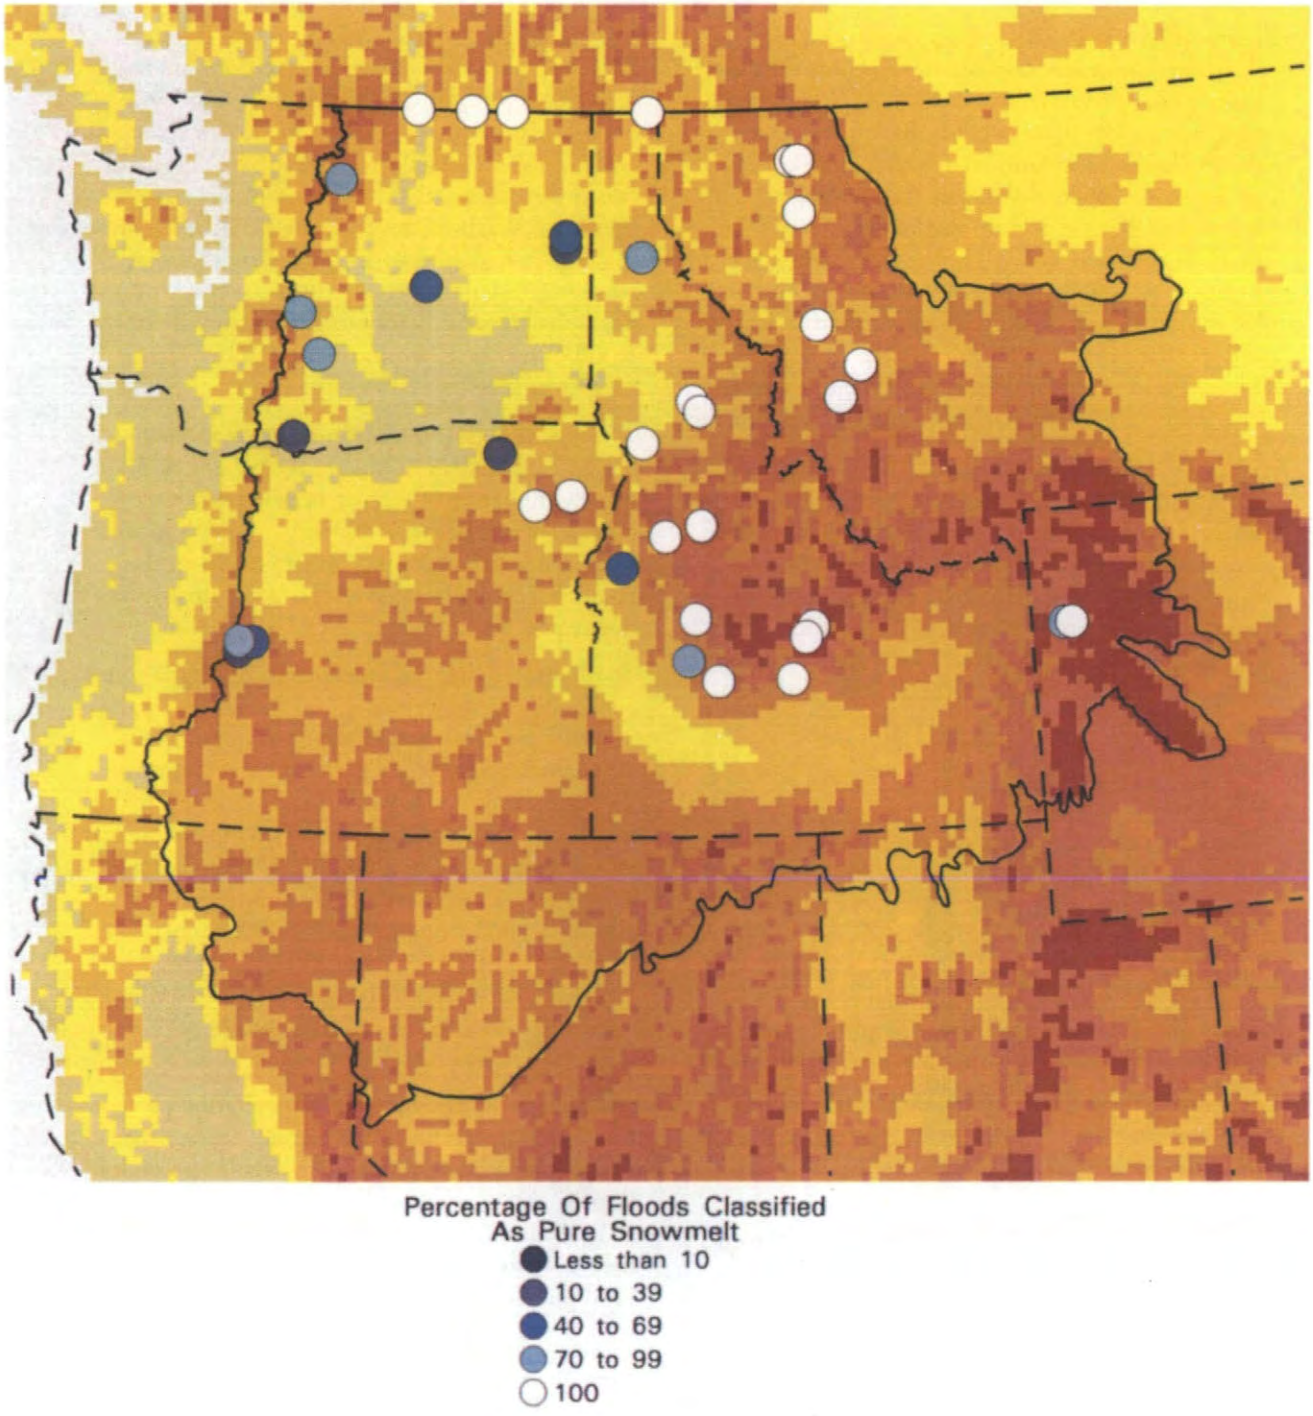
There are few cases of documented cold damage in the Basin. Therefore, to gain insight into the potential for cold damage, a model was designed to include many of the known causes for cold damage to trees (Westrick and others, in preparation). In winter, cold damage primarily occurs during a cold snap that immediately follows an unseasonably warm period. Spring damage occurs to trees when freeze follows budbreak.

Map 2.30—Total months with PDSI <-3.0 (1895-1994).

During autumn, damage occurs if freeze precedes cold hardiness. By applying this model with distributed temperature data that was generated by Thornton and Running (1996), the spatial extent of cold damage potential during three characteristic years becomes apparent.

During a characteristic cool, wet year (1982), low to moderate cold damage is possible for many areas around the Basin, mainly above 2,500 meters. Some damage to peach trees in east-central Oregon was reported during this time, but most other areas showing potential damage were above tree-line. A moist, zonal flow pattern commonly is associated with this type of climate in the Basin, causing moderately varying temperatures with few extremes.

A warm, dry year (1988) spawned a few more cold damage events. Weather patterns in this type of climate commonly are associated with a split upper-level flow that prevents frequent storms from crossing the Basin. Warmer overall temperatures allow a greater percentage of trees to come out of dormancy earlier in the spring season and to go into dormancy later in autumn. This makes them more susceptible to cold storms that can break through the split flow and pass over the area.



A more typical year is represented by temperatures in 1989. Typical northwest weather occurs when the upper-level flow pattern fluctuates between moist zonal flow and cold meridional flow. Although seasonal conditions allow normal timing of dormancy and budbreak, extremes in temperature also are possible. During this year, significant cold damage was reported in western Montana (Klein 1990).

Rain-on-Snow floods—When heavy rain falls and penetrates an existing snow cover, intense and damaging floods are possible. Harr (1981) indicated that 85 percent of landslides in western Oregon are associated with snow-melt during rainfall. Similar studies have been conducted in British Columbia (Beaudry and Golding 1985), California (Hall and Hannaford 1983), and western Washington (Harr and Cundy 1990).

Further away from the coast, a pervasive winter snow cover is typical and mid-winter rain is less common. Unlike other continental interiors, however, the Columbia River basin has a unique topographic configuration that allows frequent incursion of warm, moist air from the Pacific Ocean. This causes occasional rain to fall onto the existing snow cover. Resulting floods are less frequent but equally destructive (Cooley and Robertson 1983, MacDonald and Hoffman 1995, Zuzel and Greenwalt 1985, Zuzel and others 1983). Paleo-climate evidence suggests that ROS events caused significant flooding in the Columbia River Basin during several periods between 18,000- and 9,000-year B.P. (Chatters and Hoover 1992). Since 120 A.D., major floods (similar to the 1948 event) along the Columbia River system appear to have occurred every 140 years, except for a period between 1020 and 1390 A.D. when floods occurred at rates three to four times more frequently (Chatters and Hoover 1986).

To help understand the frequency and severity of ROS floods in the Basin, we reviewed unregulated stream gauges. All of the stations in the Wallis-Lettenmaier-Wood data set (1991) in the Columbia Basin above The Dalles were selected. Next, all floods that occurred during the months of October to February were classified as ROS events, and those that occurred in other months were classified as pure snow-melt (that is, dominantly radiation melt) events (map 2.31). Those stations in the Basin that were classified with a high percentage of ROS flood represent relatively low elevation catchments. This corroborates evidence that snow accumulations at low elevations can significantly enhance ROS floods (Harr and Cundy 1992). Even with a low percentage of ROS floods, it is interesting to note that several stations experience their heaviest floods during the infrequent ROS events (Ferguson and others, review a).

To illustrate the spatial distribution of ROS events, a simple algorithm (Ferguson and others, in review a) for determining when rain is falling on snow was applied to the Basin using available temperature and precipitation data for characteristic climate

Map 2.31—Percentage of floods classified as pure snowmelt.

years of 1982, 1988, and 1989. In all years, the model indicates rain-on-snow events are possible in many areas of the Basin. On closer inspection, areas most susceptible to ROS events are those where topography allows incursion of relatively warm, moist marine air that flows into the Columbia Plateau and up the Snake River valley from the Pacific Ocean. These areas include the Cascade mountains; northern Idaho, northeastern Washington, and northwestern Montana with valleys that open into the Columbia plateau; the Blue Mountains of northeastern Oregon; western Wyoming; and central Idaho adjacent to the Snake River.

Cool wet years (1982) are likely to have more rain-on-snow events. The cool temperatures allow low elevation snow to accumulate, whereas the frequent precipitation brings the possibility of mid-winter rain. Warm dry years (1988) are less likely to experience rain-on-snow flood events. There is little low elevation snow at these times and only occasional precipitation.

Air Quality Climate

Stagnant atmospheric patterns in the Columbia River Basin are dominated by topographic features. Surrounding mountain ranges impede mixing of air masses and create an isolated Basin atmosphere. Gaps through the mountains, however, allow a pattern of mixing that is unique to the Basin. Several components of climate that influence air quality include mixing height, precipitation, and upper level and surface winds. These components are discussed below, along with the implications of climate change on the Basin's air quality.

Mixing height—Mixing height may be considered as a level in the atmosphere above which vertical exchange of air is inhibited. Low mixing heights mean that the air is generally stagnant with very little vertical motion, and pollutants usually are trapped near the ground surface. High mixing heights allow vertical mixing within a deep layer of the atmosphere and good dispersion of pollutants. Mixing heights were calculated by the Western Regional Climate Center.[3] The stations analyzed included: Quillayute, Washington (58 m elevation), the only station on the Pacific coast; Salem, Oregon (61 m); Medford, Oregon (421 m), between the coast and Cascade mountain ranges; Spokane, Washington (722 m); Boise, Idaho (871 m), inside the Basin; and Winnemucca, Nevada (1,310 m), just south of the Basin in northern Nevada. Data included approximately 1,000 observations from the period between 1966 and 1989.

Within the Basin, the mean summer mixing height is about 1,800 meters at Spokane and Boise. The range of mixing heights, however, includes levels below 900 meters, especially at Boise where topographic constraints from the Snake River valley are even more dominant than the overall Basin topography.

To illustrate potential areal extent of stagnant air, constant height levels of 1,000 meters and 1,400 meters were plotted over the basin topography. Stagnant air may occur in the central plateau of the Basin and the lower Snake River valley if the mixing height is constant at 1,000 meters, near the lowest summer mixing heights. If the mixing height is constant around 1,400 meters, there is relatively good dispersion in the central plateau of the Basin. High basins and some high valleys in Oregon and western Montana may trap air, however, and cause pockets of stagnation.

Rain—Airborne pollutants may fall out of the atmosphere by attaching to precipitating particles. Liquid precipitation (rain) is more efficient at scavenging gas and particles than solid precipitation (such as snow and hail). Therefore, a simple analysis of rain days per month was conducted to help determine the frequency of wet deposition onto plants and into soils and snowcover.

To determine rain days in wildland regions, data from all National Weather Service (NWS) cooperative observation station sites above 900 meters

[3] P.O. Box 60220, Reno, Nevada 89506-0220.

elevation were selected. Days of rain were defined as those days with measured precipitation and mean temperatures greater than 5° C.

Rain days per month were calculated for January during three characteristic climate years: 1982, 1988, and 1989. In all years, there were few days of mid-winter rain at elevations above 900 meters. Although significant precipitation occurred during winter 1982, most fell as snow, and rain was confined to lower elevations in eastern Oregon and western Idaho. The "normal" year of 1989 again showed few mid-winter rain days, mostly at lower elevations.

The number of rain days per month became greater than snow days per month as seasonal temperatures increased. Slightly fewer stations observed rain during April in 1982 than other years because snowfall continued through spring that year. In 1988, several stations throughout the Basin experienced 50 to 75 percent days with spring rain. In 1989, most stations experienced at least 25 percent days with rain, which is typical of spring.

Summer precipitation in the Basin is dominated by atmospheric convection. During wet years such as 1982, a large number of stations experienced more than 50 percent days with rain, especially in places where summertime convection dominates precipitation. In 1988, no station measured significant precipitation as dryness pervaded the Basin. During a normal year, typical summer patterns of precipitation prevailed with most rain days occurring in places where convection is common such as eastern Idaho and western Montana.

During autumn, convection remains important in precipitation distribution. In addition, the significance of frontal and orographic precipitation begins to increase, but snow also may occur. In 1982, most of the mountain sites show over 25 percent of the days with rain. Cooler than normal seasonal temperatures also may have caused days with snow. In 1988, few stations measured more than a few days with rain. Most of those occurred in Idaho and western Montana where convection probably remained important. During a typical year, most stations observe about 25 percent of days with rain.

Upper level winds—Winds in the upper atmosphere may carry buoyant pollutants long distances. Land managers have shown concern about the possibility of pollutants from the Basin reaching the Grand Canyon. This may occur if upper level winds over the Basin are strong northerly.

Only two stations with the Basin regularly report upper-air data: Spokane, Washington and Boise, Idaho. The distribution of wind speed and direction was calculated by the Western Regional Climate Center[4] for Spokane and Boise. Winds at the 700 millibar (mb) level are shown because that level (about 3,000 m) usually is above the influence of terrain surrounding the Basin and is most likely to carry pollutants out of the Basin.

These results suggest that strong northerly winds are most common at both locations during winter. At Spokane, the mean winter 700 mb wind direction is westerly with a normal variation between SSW-W-NNW. Nine percent of the winds have a northerly component with speeds greater than 11 miles per second (m/s). Over Boise, winter winds prevail from the WNW, and 15 percent have a strong (greater than 11 m/s) northerly component. Although there is very little biomass burning in the winter, the northerly winds could scour away pollution trapped under the Basin's frequent winter inversion. Whether the scoured components reach the Grand Canyon or deposit along the way is unknown. Strong northerly winds are possible during spring and autumn burning seasons, but are rare. Summer northerly winds usually are too weak to transport material for long distances.

Surface winds—Winds near the earth's surface are most efficient at transporting pollutants that are either nonbuoyant or neutrally buoyant. These wind types can carry smoke from biomass burning into nearby towns and cities. In addition, surface winds can carry pollutants from industrial sources into wildland areas.

[4] P.O. Box 60220, Reno, Nevada 89506-0220.

Near the ground surface, winds are strongly influenced by small undulations in topography. There are not enough observations of surface wind to show the true variation in wind, so a simple mesoscale wind model was adapted to analyze the effect of surface wind on pollution transport (Ferguson and others, in review b).

Surface wind during winter primarily is controlled by pressure gradient forces between a persistent region of high pressure over the continent and frequent low centers from approaching Pacific storms. This pressure gradient causes strong easterly winds to persist through the Cascade mountain passes. It also causes much of the stagnant air, which is trapped under the frequent winter temperature inversion, to be pulled against the eastern Cascades (Steenburgh and others 1997). Passing storms cause winds to accelerate over the higher ridge tops, especially in the Rocky mountains. Converging winds are common, such as in the lee of the Blue mountains and head of the Snake River. Stagnant winds also occur, usually below the persistent inversions (see the discussion on central Columbia and Snake River plateaus).

During summer, surface winds are dominated by downslope flows caused by cooling air that drains into the valleys at night. An onshore flow also prevails, causing weak to moderate westerly winds through the Cascade passes. Areas of weak convergence or stagnation occur most frequently in valleys and basins where the downslope winds are trapped by surrounding topography.

Implications of global climate change on air quality in the Basin—Atmospheric concentrations of greenhouse gases are increasing. Major carbon constituents that contribute to the greenhouse effect are increasing at the following known rate: CO_2 - 0.4 percent or 1.5 parts per million (ppm) per year; CH_4 - 0.9 percent or 0.015 ppm per year; CFCs - 4.0 percent or 0.015 ppm [Intergovernmental Panel on Climate Change (IPCC) 1990 and 1992]. A recent report by the Pacific Global Change Research Program (PacGCRP) summarized the effective sources and sinks of greenhouse gases and discussed possible implications for management (Bytnerowicz and others, in press). For example, major sources for CO_2 are listed as decomposition, respiration, biomass fires, volcanic emissions, fossil fuel burning, and changes in land use. It also was recognized, however, that more nitrogen can produce a cofertilization effect in the terrestrial biomass, which would lead to sequestration of additional carbon. In addition, a discrepancy in the global nitrous oxide budget was attributed to emissions from forest soils, and certain management practices could minimize these emissions. The PacGCRP report also explains that sources of atmospheric methane include cattle, wetlands, and termites. Like CO_2 and nitrous oxides, CH_4 emissions can change by altering management practices.

Another implication of increasing greenhouse gases is their possible effect on global climate. Although uncertainty remains in the rate and magnitude of expected change, a general warming trend due to increasing concentrations of greenhouse gases is almost certain. We examined a climate change scenario that considered the regional effect of doubling the global atmospheric concentrations of carbon dioxide ($2xCO_2$) on regional climate (Ferguson 1997). The following list summarizes possible effects on air pollution:

- Greatest warming over high-latitude continents could result in less intense Arctic influence and thus weaker temperature inversions during winter.
- Continents could warm more than oceans, resulting in higher summer mixing heights.
- Decreased snow cover could cause less intense winter stagnation and earlier seasonal discharge of pollutants held in the snowpack.
- Increased convection over continents could lead to more wet deposition in spring and summer with less frequent drought in southeast portions of the Basin.

- Decreased soil moisture during summer could result in greater summer drought, especially in the central Basin.
- Fewer, but stronger, winter cyclones could cause less frequent but more significant disruption of winter stagnation.

Soil Features

Soil productivity is defined as the inherent capacity of a soil to support the growth of specified plants, plant communities, and soil biota (USDA Forest Service 1991). The Basin contains hundreds of soils that vary greatly in their parent material, climate, topography, vegetation, and age; this variation results in a broad range of productivity.

Soils were not mapped, nor productivity information collected, for this assessment due to the limited time available. Instead, indicator variables and an expert panel were used to evaluate soil productivity. Both a regional and a subregional assessment were completed and will be published in a separate technical paper.

Using ecoregions and subregions (map 2.4) delineated by Bailey and others (1994a), the panel divided the Basin into five distinct areas:

- Province M333
- Province M332, including eastern portion of Section 331A
- Province 342, including western portion of Section 331A
- Section M242C, including a small part of Section M261G
- Section M331D

The expert panel contributed to the assessment by providing the following information:

- A general productivity overview of each area.
- A description of the impacts of management activities on these indicators and processes.
- An estimation of productivity trends.
- Recommended actions for maintaining long-term soil productivity.

The findings of the expert panel are summarized below by province.

Province Descriptions

Province M333 Northern Rocky Mountain Forest-Steppe-Coniferous Forest-Alpine Meadow—Province M333 occurs in northeastern Washington, northern Idaho, and northwestern Montana. It is mountainous with elevations that range from approximately 370 to 3,000 meters. This area has a maritime-like climate, except in the east where a continental climate prevails. The average annual precipitation varies from about 400 to 2,500 millimeters. The dominant vegetation types are cedar hemlock pine, western white pine, and Douglas-fir forests. Volcanic ash covers most of the area.

Soil productivity of Province M333 is generally good because of the volcanic ash soils (Geist and Cochran 1991) and the presence of favorable temperatures and precipitation (maritime climate and low-to-moderate elevations). The most productive areas are the low- to mid-elevation sites where neither temperature nor moisture are considered limiting. The least productive soils occur west of the Columbia River and are shallow and stony, and lack volcanic ash.

Northern Rocky Mountain forests have generally low susceptibility to surface fuel accumulations because of their long fire cycles and relatively high productivity. Fuel accumulations remain close to historical norms. These systems are also more capable of replacing soil organic matter, coarse woody debris (larger than 10 cm in diameter), and nitrogen losses than lower productivity systems. In most cases, these forests can be considered moderately buffered against soil damage and in relatively good condition. However, where western white pine mortality from blister rust has been high and large amounts of dead material have accumulated,

these fuels can represent a substantial risk for causing soil damage if the site were to burn when fuels are dry.

Province M332 Middle Rocky Mountain Steppe-Coniferous Forest-Alpine Meadow Province—Province M332 occurs in central Idaho, westcentral and southwestern Montana, and northeastern Oregon. Elevations generally range from approximately 300 to 3,700 meters. This province includes mountains with narrow valleys, basins, alpine meadows, and breaklands. Most of the higher elevations have been glaciated. Maritime climate, westerly winds, and orographic precipitation yields less than 500 millimeters at the lowest elevations to over 750 millimeters in mountainous areas. Vegetation is dominated by Douglas-fir, ponderosa pine, grand fir, sagebrush steppe, and fescue/wheatgrass grassland.

The soils of Province M332 are only moderately productive because of their shallow depths associated with mountain locations, cold temperatures, and low precipitation in some areas. The most productive soils occur in valleys and basins where they are often deep, have high volcanic ash content, and receive higher precipitation.

Heavy fuel accumulations and dense stand conditions in some areas place long- and short-term soil productivity potential at risk from wildfire. In contrast, where high fuel and/or dense stand conditions are absent, the risk of potential damage to soils from wildfire is minimal. Where heavy fuels exist (especially on the most sensitive soils), future soil conditions are likely to degrade when wildfires do occur.

Province 342 Intermountain Semi-Desert—Province 342 consists of plains, tablelands, and plateaus in central Washington, southcentral and southeastern Oregon, and southern Idaho. Elevations range from approximately 60 to 2,400 meters. This area has a semi-arid, cool climate. Average annual precipitation varies from about 100 to 625 millimeters. Dominant vegetation types are sagebrush steppe and grassland.

Low productivity soils are common in Province 342 because of the sparse precipitation and low soil organic matter levels that occur throughout much of the province.

Even though moisture is the most limiting factor for these soils, organic matter and nitrogen values are also generally limiting. Organic matter amounts vary with moisture throughout the province. Riparian/wetland areas and high elevation forested and grass/shrub sites have the highest organic matter; the young lava flows, sand dunes, and saline-sodic soils have the least organic matter. In addition, extensive fires in some parts of the province have reduced organic matter and nitrogen contents to critical levels. This situation has often resulted in the expansion of cheatgrass monocultures, which are susceptible to repeated burn cycles that further degrade soil productivity. Although most forests in this area produce low amounts of fuels, high fuel accumulations that contribute to hot fires can occur on more productive sites.

Section M242C Eastern Cascades (including northern portion of Section M261G)—Section M242C occurs on the eastern slopes of the Cascades in Oregon and Washington. The upper Klamath portion of the Modoc Plateau in southern Oregon is also included in this discussion. Average annual precipitation of this area varies from about 250 to 4,000 millimeters and elevations range from approximately 90 to 3,000 meters. The dominant vegetation is a mixed coniferous forest dominated by Douglas-fir and ponderosa pine.

The soils of Section 242C have moderate to high productivity. The most productive soils of this area have formed from volcanic ash or pumice at low to moderate elevations with moisture and temperature regimes that are favorable for plant growth.

Large portions of this area accumulate substantial amounts of fuels and have high probabilities of stand replacement wildfires. Stands in this condition have a high risk for losses of organic matter, coarse woody debris, and nitrogen. The relatively

coarse woody debris, and nitrogen. The relatively low productivity of many of these forests and their soils means that lost organic matter will be replaced slowly, perhaps taking decades to centuries to replenish. However, in areas where high fuels and/or dense stand conditions are absent, the threat to organic matter loss from wildfire is less.

Section M331D Overthrust Mountains—Section M331D occurs in southeastern Idaho and western Wyoming. The landscapes of this area have been shaped by overthrust faulting and glaciation, which has created steep rugged mountains with narrow to broad valleys in a general north-south orientation.

Most of this area occurs within approximately 2,000 to 2,700 meters of elevation with some of the section extending to approximately 4,200 meters. The climate is a semi-arid steppe with most of the 400 to 1,000 millimeters of annual precipitation occurring in the fall and winter as snow. Vegetation is mixed, including coniferous forest and sagebrush/grassland with Douglas-fir, lodgepole pine, and aspen occupying the northern aspects. Alpine forb plant communities are common at higher elevations. The climate is cool, with cold soil temperature regimes and sagebrush/grassland communities in broad valley settings.

The soils of section M331D are generally moderately productive. The greatest productivity limitations are cool temperatures and short growing seasons due to the high elevations characteristic of this setting. Moisture is also limiting in some areas.

Although less extensive, similar conditions of fuel accumulation and dense stand conditions occur as in Section M242C. Where such conditions exist, both the long- and short-term productivity potential of the soil can be at risk from wildfire. Where high fuel and/or dense stand conditions do not exist, these forests are considered to be in good condition. Where heavy fuel loads exist on the most sensitive soils, future soil conditions are likely to degrade when wildfires occur.

General Effects of Management Activities

The importance of organic matter to long-term and short-term soil productivity is well documented. Organic matter is especially important for soil water retention, cation exchange, nutrient cycling, and erosion control (Page-Dumroese and others 1991). Organic matter buried in the soil improves aeration; increases structure, infiltration, percolation, and moisture retention; and protects the soil from compaction. As residues decay, they are incorporated into the soil and form organic reserves (Harvey and others 1987). Soil organic matter is an important source of nitrogen, sulfur, phosphorus, calcium, magnesium, and potassium for plant growth (Meurisse and others 1991, Page-Dumroese and others 1991).

Natural resource management activities can reduce soil productivity through the loss of organic matter and nutrients. These losses can be caused by erosion, topsoil displacement, damaging fires, and over-utilization. Management activities can also degrade the physical properties of soil, especially through compaction from equipment or livestock use.

Soil loss from erosion affects long-term soil productivity by reducing nutrient pools, water-holding capacity, and soil biotic populations, as well as by directly damaging vegetation (Megahan 1991, Swanson and others 1989). The most severe and long-lasting disturbances of soil erosion are deep-seated, mass erosional events. Surface erosion, however, on agricultural and mountainous lands is more widespread and can cause greater cumulative reductions in soil productivity. In addition, surface erosion reduces soil productivity disproportionately because the nutrients content and water-holding capacity of soils are highest near the surface in the organic layer and the uppermost soil horizon (O and A horizons) and decrease markedly with depth. Short-term growth is generally reduced when topsoil is removed, and effects are commonly greater on shallow soils than deep soils (Childs and others 1989).

Soil productivity can be reduced by natural and man-caused disturbances that accelerate soil erosion, including road construction, prescribed fire, grazing, cropping, and timber harvest. In non-intensively managed forests and rangelands, wildfires have the greatest potential of reducing soil productivity over large areas (Megahan 1991). Although the areal extent of soil displacement from logging activities rarely exceeds 30 percent within harvested areas, displacement of topsoil can decrease soil productivity dramatically (Childs and others 1989). Such displacement disrupts important biological activities and can increase surface erosion potentials by removing protective litter layers and reducing the infiltration capacity of the soil. Fire and displacement effects may leave soils in a condition with accelerated erosion potential for approximately a decade. Road construction increases the probability and size of mass erosion events and greatly accelerates surface erosion. Road effects commonly persist for the life of the road, although the amount of erosion normally decreases dramatically after the first few years (Megahan 1974).

Soil bulk density is the ratio of the mass of dry solids to the bulk volume of the soil. Soils that are loose and porous, such as volcanic ash soils, have low weights per unit volume; soils that are more compact have high values. Because the particles of sandy soils generally lie in close contact, they tend to have high bulk densities. The low organic matter content of sandy soils also contributes to their high bulk density. On the other hand, the particles of finer-textured surface soils are comparatively well-granulated, a condition encouraged by their relatively high organic matter content. As organic matter content increases, aggregation of the mineral soil particles increases and the soil becomes more porous, which results in lower bulk density values.

Maintenance of bulk density is crucial to sustaining long-term productivity (Froehlich and McNabb 1984). As management activities become more intense and concentrated in an area, bulk density commonly increases due to increased traffic. Increased traffic not only results in surface bulk density increases, but can be measured at depths of up to 30 centimeters in some cases. Recovery from surface compaction can occur within approximately 50 to 80 years after damage if there are sufficient organic matter inputs and freeze/thaw cycles to ameliorate compaction effects. Recovery of compacted subsoils probably requires upwards of 200 years. Increases in soil bulk density result in reduced seedling growth and less obvious reductions in the long-term nutrient content, porosity, and infiltration of affected soils.

According to Wells and others (1979), fire can have four generally negative impacts on soils:

- Removal of protective surface layer organic materials.
- Volatilization of large amounts of nitrogen and smaller amounts of other nutrients.
- Conversion of some nutrients into soluble forms that can be lost by leaching.
- Heating of the soil and alteration of its physical, chemical, and biological properties.

The burning of plant materials commonly volatilizes large amounts of nitrogen and lesser amounts of sulfur. Loss of nitrogen can potentially limit productivity because it is both the nutrient lost in the greatest amounts and the nutrient most frequently limiting for plant growth (McNabb and Cromack 1990). In general, the hotter the burn the greater the potential for soil damage and nutrient loss. Prescribed fires can normally be conducted during times when conditions will not result in substantial damage to the soil (that is, when soils and fuels are moist). However, wildfires can occur when soils and fuels are especially dry and can cause nutrient losses and water repellency (Debano and others 1970) resulting in overland flow, rill, erosion and soil productivity loss.

In addition to the soil productivity losses that can result from erosion, compaction, and severe burning, these disturbances can also lead to increased activity of endemic root pathogens. Soil distur-

bance can induce stress in the hosts of these pathogens and make them more susceptible to damage (Harvey and others 1989). This situation can lead to productivity losses and changes in vegetation composition and structure.

Estimate of broad productivity trends—The link between impacts on soil properties and long-term soil productivity change is not well-established. Because relatively little long-term data is available, most research results are for shorter periods of time, which limits their utility in understanding long-term soil productivity changes. Despite this fact, some shorter period research studies have documented soil productivity declines following soil disturbance (Froehlich and McNabb 1984, Helms 1983, Powers and others 1990). A National Long-Term Soil Productivity Research Program has been established within the FS to provide needed data to help understand the effects that management activities have on soil productivity (Powers and others 1990).

Expert panel estimates of soil productivity trends within the Basin ranged from stable to decreasing depending on the area examined. The trend for any particular area can generally be estimated based on the types and amounts of soil-disturbing activities that have occurred (that is, the greater the disturbance, the greater likelihood that soil productivity has been decreased).

From presettlement time to the present, the amount of soil in the Basin disturbed by land management activities has generally continued to increase. Some of these activities cause only minor soil disturbance while others cause long-lasting impacts. For example, soil productivity is probably relatively unchanged in most wilderness areas and other similar settings because there has been little physical disturbance or changes in organic matter levels. In contrast, some portions of the Basin have been intensively managed for many decades. Areas that have experienced substantial amounts of erosion, displacement, hot or multiple burns, or over-utilization of plant materials have generally experienced a decrease in soil organic matter and productivity. Similarly, areas that have had extensive equipment operations and/or livestock grazing have experienced increased soil compaction, which also decreases soil productivity.

Where fire suppression has been effective for long periods, soil productivity may be higher than historical ranges due to subsequent enrichment of organic matter and nitrogen. Intense fires will eventually burn such areas, however, and may result in high losses of organic matter, coarse woody debris, and nutrients through rapid oxidation, volatilization, and subsequent erosion by wind and water. Productivity will likely decline under these conditions.

In some localized areas, the productivity of soils may be increasing on sites that are not compacted, displaced, or severely burned, especially where nitrogen-fixing species (such as alder and ceanothus) contribute effectively to nitrogen enrichment.

Organic-matter levels of most soils within the Basin were generally in equilibrium with their environment prior to the initiation of logging, grazing, and farming. Organic matter and nutrients were balanced through recycling resulting in a situation where little loss in these elements occurred on most sites. Logging, grazing, and farming of soils within the Basin, however, typically resulted in some loss of organic materials and nutrients on a site due to removal of logs, herbivory, and agricultural development. After an area has been in management for some time, a new and lower equilibrium level of organic matter is reached. The exact level depends on the original amount and the management practices used. Areas where soil productivity conservation practices were implemented generally maintained higher levels of productivity than areas where such practices were not observed.

Recommended practices to maintain long-term soil productivity—Soil compaction is a major concern throughout all ERUs. A strategy that involves limiting the amount of compaction from equipment or livestock use would help

maintain long-term productivity. One such strategy is to limit operations to times when the least damage is likely to occur to soils (for example, when they are dry). Selecting equipment that will cause the least soil compaction can also help maintain productivity. Examples of minimal impact timber harvesting methods include use of low ground pressure equipment, grapple pile machines rather than dozers, and cable yarding systems or helicopters when possible.

Maintaining proper amounts of organic matter and coarse woody debris is also a major concern for all ERUs because of the importance of these materials to ecosystem function. In highly productive forests, a balance between too much and too little coarse woody debris is desirable. Too much fuel on a site often contributes to severe fires that may adversely impact soil productivity; however, too little fuel may also contribute to impaired long-term soil productivity. Examples of recommendations appropriate to coarse woody debris management are provided by Graham and others (1994).

Whole tree harvesting is generally not consistent with coarse woody debris management recommendations (Graham and others 1994) on most soils of the Basin. Similarly, the removal of slash containing tops and branches from most sites can negatively impact organic matter and nutrient cycles. Burning of these materials in place causes much less negative impacts to the soil, especially if they can be left on the ground for a winter season prior to burning. Leaving slash on the ground through the winter leads to a high probability that nitrogen and other nutrients in the foliage will be incorporated into the soil. Burning when soil surface layers are high in moisture can prevent development of water-repellent conditions.

Desirable site-preparation for tree regeneration includes burning or using mechanical treatments that cause no more disturbance than necessary to achieve sufficient seedling survival. Spot removal of surface soil layers (scalping) may decrease soil productivity; however, scalping may be required to alleviate special competing vegetation problems on certain sites.

Fire is an important tool for managing the organic component of soils. Severe intensity and/or long duration fires can cause organic matter loss, create hydrophobic soils, increase erosion, and consume nutrients. Desirable fire prescriptions are those that maintain as much of the surface organic layer as possible while meeting objectives for new vegetation establishment. In addition, prescribed fires that leave adequate amounts of coarse woody debris onsite maintain long-term productivity.

The following practices can protect soil organic matter and bulk density from livestock grazing:

- Leaving enough ungrazed plant material on site to sustain the supply of soil organic matter and litter.
- Placing salt away from riparian areas.
- Providing alternate water sources other than natural streams, if possible.
- Using grazing systems that keep livestock out of riparian areas during hot summer months.
- Herding or fencing livestock out of riparian areas.
- Delaying grazing following fire until the rangeland vegetation has recovered.

Soil productivity restoration—Preventing soil damage and productivity loss is usually easier than restoring soil productivity. In those situations where soil productivity restoration is required, two treatment approaches are commonly used dependent on management objectives. The first of these approaches is to restore organic matter and coarse woody debris to the soil. This objective could be accomplished by leaving areas undisturbed and allowing sufficient time for organic matter recovery to occur. Where organic matter loss is the result of erosion, controlling the erosion is often necessary before recovery can begin. The second common approach used in restoring soil productivity is to ameliorate increased bulk densities created by compaction. This objective is com-

monly achieved through use of subsoiling equipment designed to break compacted layers, which results in more favorable soil bulk densities for plant growth. Despite the fact that lower soil bulk densities can often be achieved through such treatments, not all of the physical properties of the soil are commonly restored to pre-disturbance conditions by such treatments.

Hydrology Features

Primary objectives for the hydrologic analysis of the Basin included:

- Basic description of the hydrologic environments present.
- Identification of relative hydrologic hazard and management potential differences across the Basin.
- Evaluation of recent hydrologic pattern and process changes.
- Description of probable effects of management on hydrologic system integrity.

Realization of these objectives involved characterization of each 6th-field subwatershed within the Basin using the following general types of data:

- Morphometric attributes
- Probable peak flows
- Biophysical environment composition
- Climatic attributes
- Stream type group composition
- Hydrologic hazard ratings
- Stream channel sensitivity ratings.

A subsample of 357 6th-field subwatersheds was also used to facilitate description of current stream and valley bottom type composition and to illustrate recent historic changes in riparian vegetation by different valley bottom type settings. Available fishery habitat data were also analyzed to describe finer scale channel unit characteristics by generalized stream type groups.

Information concerning each 6th-field subwatershed was aggregated into two levels of hierarchical aquatic ecological unit description for analysis:

- Hydrologic subregions (Jensen and others in press).
- Hydrologic regions or ERUs.

Basic descriptions of hydrologic pattern and process relations across the Basin are provided for the regional or ERU level of analysis conducted. Summarizations of hydrologic pattern and process relations at the subregional scale are being developed and will be published at a later date.

To facilitate synthesis of hydrologic data with other SIT staff information, 6th-field subwatershed data were summarized by ERU and displayed in various tables and figures. The following discussion provides a brief description of how these ERU data tables and figures were constructed. A description of the general effects of management activities on selected hydrologic patterns and processes follows that discussion.

ERU Characterization Procedures

Biophysical environment variables were used to develop an initial hydrologic region map of 14 settings within the Basin. These hydrologic regions were further modified in the development of ERUs as described previously in this chapter. Initial analysis of the hydrologic regions indicated significant differences in unregulated 4th-field subbasin stream hydrograph characteristics across the Basin. Classifications were developed for each unregulated, gauged 4th-field subbasin of the Basin based on its hydrologic flow type response characteristics (for example, ground-water or snow-melt dominated). Relativized percent composition of these flow type classifications were then attributed to each ERU based on subsample subbasin information (table 2.12).

Table 2.12—Relativized percent composition of different hydrologic flow type regimes by ERU, as determined by unregulated subbasin samples.

	Stream Flow Regime				
Ecological Reporting Unit	Ground Water Influenced	Snowmelt Influenced	Snow and Rain Influenced	Winter Rain Influenced	Harsh Intermittent Influenced (seasonally dry)
Northern Cascades	8	38	54	--	--
Southern Cascades					
Upper Klamath					
North Great Basin					
Columbia Plateau	9	27	9	54	--
Blue Mountains	--	25	75	--	--
North Glaciated Mountains	10	57	33	--	--
Lower Clark Fork	--	10	90	--	--
Upper Clark Fork	--	100	--	--	--
Owyhee Uplands	--	50	38	--	12
Upper Snake	--	33	67	--	--
Snake Headwaters			--		
Central Idaho Mountains	3	71	23	3	--

The composition of different biophysical environments that have strong relations to the hydrologic characteristics of each ERU are presented in tables 2.13a and b (lithology), table 2.14 (subsection groups), and table 2.15 (regional potential vegetation types). Construction of these tables involved summarization of average biophysical environment composition values for each 6th-field subwatershed within an ERU. Results are reported as:

- Constancy (the percent of the 6th-field subwatersheds in which a particular environment was present).
- Average composition when present (the average composition of a particular environment found in the 6th-field subwatersheds).
- Total average composition (the average composition of an environment across all 6th-field subwatersheds of an ERU, which includes 0 values).

Selected 6th-field subwatershed morphometric and climatic variable summaries are presented by ERU in table 2.16. These values reflect aggregation of average 6th-field subwatershed data as determined by PRISM average annual precipitation maps, 24-hour storm intensity maps, 2-kilometer raster-based climatic data extrapolations from the mountain climate simulator, regional USGS peak flow regression models, and 90-meter digital elevation modeling.

Table 2.13a—Primary lithologic composition of subwatersheds by Ecological Reporting Unit.

ERU Name	Lithology Code[1,2]	Percent Constancy	Average Composition When Present	Total Average Composition

[1] See table 2.13b for lithology descriptions.

[2] Only those lithologic types having constancy values greater than 33 percent are displayed in this summary table.

Table 2.13b—Description of lithology codes presented in table 2.13a.

Code	Lithology Description	Code	Lithology Description	Code	Lithology Description
1	Alkalic intrusive	15	Granitic gneiss	29	Meta-siltstone
2	Alluvium	16	Interlayered meta-sedimentary	30	Metamorphosed carbonate & shale
3	Argillite & slate	17	Lake sediment and playa	31	Mixed carbonate & shale
4	Calc-alkaline intrusive	18	Landslide	32	Mixed eugeosynclinal
5	Calc-alkaline meta-volcanic	19	Loess	33	Mixed miogeosynclinal
6	Calc-alkaline volcanoclastic	20	Mafic gneiss	34	Open water
7	Carbonate	21	Mafic intrusive	35	Quartzite
8	Conglomerate	22	Mafic meta-volcanic	36	Sandstone
9	Dune sand	23	Mafic pyroclastic	37	Shale and mudstone
10	Felsic pyroclastic	24	Mafic schist & greenstone	38	Siltstone
11	Felsic volcanic flow	25	Mafic volcanic flow	39	Tuff
12	Glacial drift	26	Meta-conglomerate	40	Ultramafic
13	Glacial ice	27	Meta-sandstone	41	Unclassified
14	Granite	28	Meta-sedimentary phyllite & schist

[1]Only those potential vegetation types having constancy values greater than 33 percent are shown in this summary table.

Estimated stream type group composition of each ERU is presented in table 2.17 which reflects averages across all the 6th-field subwatersheds within an ERU. These values were obtained from a series of workshops where local experts described dominant stream type group composition of previously mapped subsection group slope phases. This information was associated to each 6th-field subwatershed of the Basin by a GIS and used to produce channel sensitivity ratings across the Basin.

Average valley bottom type (table 2.18) and stream type (table 2.19) compositions were associated to each ERU based on subsample information obtained within 357 6th-field subwatersheds. These data were used primarily in the identification of key biophysical environment variables for watershed classification efforts (Jensen and others in press).

Selected fishery habitat variables were analyzed by relating habitat components to stream type settings for each ERU. These data were also further stratified by watershed disturbance classes inferred from road density criteria. Fishery habitat components represent a finer-scale aquatic pattern. Therefore, only general relationship trends were detected in the interpretation of this data at the ERU level. Increasingly detailed observations of trends in this data set were achieved by hydrologic subregion stratification; however, space limitations preclude description of these results in this document. Results of fishery habitat analysis by ERU and hydrologic subregion will be presented in future publications.

Relative differences in hydrologic hazard and stream sensitivity indices between ERUs were described in this study. An example of this characterization is provided in figure 2.4, which displays hydrologic recovery potential differences by ERU. The box plot presented in figure 2.4 displays averages, 95 percent confidence levels, and ranges of relative interpretation ratings for each ERU, based on a summary of the 6th-field subwater-sheds within an ERU.

The numbers presented in this figure range from 0 to 100 percent and reflect cumulative frequency values, which indicate the percent of other 6th-field subwatersheds within the Basin that possess similar or smaller absolute values for a given interpretation rating.

Interpretation ratings were further summarized through calculation of Sorensen similarity coefficients between each ERU (table 2.20). These ratings display the total similarity between the ERUs, based on all subwatershed hydrologic hazard and stream channel sensitivity ratings. Values of 48 to 65, 66 to 82, and 83 to 99 percent similarity are expressed by low, moderate, and high class ratings, respectively, in this table. Narrative summaries of the hydrologic feature information described above are presented by ERU later in this chapter..

Effects of Management Activities on Hydrologic Systems

> "Although the river and the hillside do not resemble each other at first sight, they are only extreme members of a continuous series, and when this is appreciated, one may fairly extend the 'river' all over the basin and up to its very divides. Ordinarily treated, the river is like the veins of a leaf; broadly treated, it is like the entire leaf."

This lucid observation of William Morris Davis in 1899 on watershed process forms the basis for this discussion of the effects of management activities on hydrologic systems.

In both aquatic and terrestrial systems, the quantity and quality of water and its rate of movement determines the primary characteristics of the ecosystem. In most terrestrial habitats, water is the limiting factor to primary productivity and is the primary mechanism for the movement of energy and material through the ecosystem. Given these pivotal roles of water in the ecosystem, the careful management of the hydrologic system is critical to the human use of any ecological system.

"Hydrology is the study of the interrelationships and reactions between water and its environment in the hydrologic cycle" (U.S. Civil Service Commission USGS 1966). In this context, "environment" is broadly defined to include all ecological processes that affect water in the hydrologic cycle. It follows, therefore, that any discussion of the effects of management activities on hydrologic systems should focus on the hydrologic cycle (fig. 2.5).

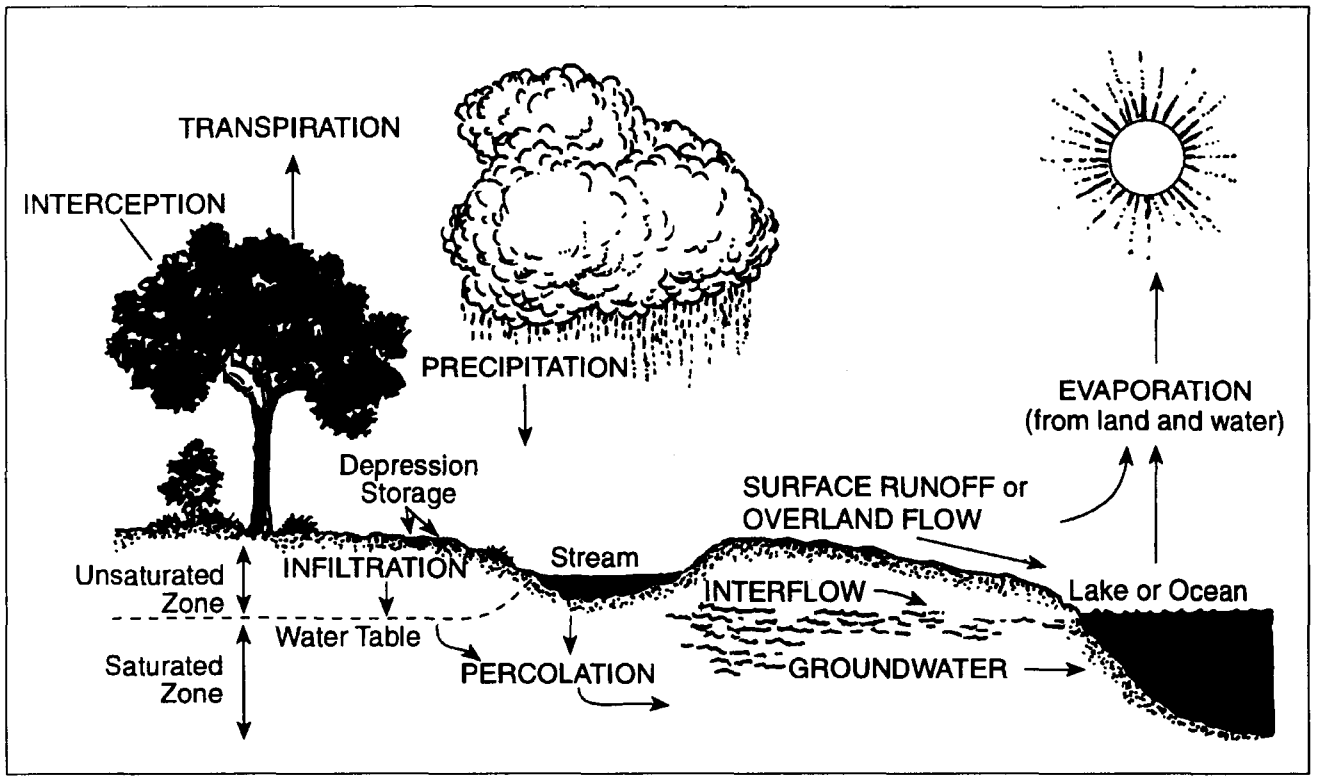

Figure 2.5—The hydrologic cycle.

The hydrologic cycle describes the pathways water follows as it moves in its endless cycle around the earth. Solar energy drives the system in many ways, primarily through evaporation of oceans and other surface water features. This water vapor then moves with winds over land areas and returns to earth as precipitation under a variety of conditions, as either rain or snow. Very few land and water management activities significantly affect precipitation on a large scale, but several kinds of activities common in the Basin do have localized effects. Extensive removal of vegetation cover and litter may cause a local increase in land surface reflectance of solar radiation, which in turn reduces the heat absorbed. Bare ground also tends to cool more at night than ground insulated by vegetation. Both of these factors contribute to a reduction in convective activity that forms cumulus clouds and thunderstorms. On a more local scale, openings in forest tree canopies can result in some redistribution and concentration of snow, which in turn changes the pattern and timing of snow melt.

Most precipitation is caught by vegetation with minor amounts of it stored on leaf surfaces, as well as by litter and debris on the ground surface. The remaining precipitation runs off the leaves and down stems or trunks, concentrating at the base of a plant. The portion of precipitation stored on leaf surfaces (interception) then evaporates or sublimates back to the atmosphere. Because interception is a function of vegetation cover, activities that reduce or increase vegetation affect this process. In a forested environment, tree canopy removal through harvest or fire reduces interception

surfaces; conversely, increasing tree canopy density through fire suppression increases interception surfaces. In a grassland or shrubland environment, grazing and fire reduce interception surfaces, whereas fire suppression with subsequent plant succession to increased shrub cover and woodlands increases interception. In an agricultural environment, perennial crops, particularly those with complex structure such as orchards, increase interception surfaces. Annual crops that only occupy the site for part of the year decrease interception surfaces. Another important aspect of interception is the effect it has on soil erosion and sediment production. Vegetation and litter layers dissipate the kinetic energy in rainfall, thereby reducing its erosive potential. Activities that increase vegetation or other soil cover reduce surface erosion and, therefore, the potential for sediment to be introduced into aquatic ecosystems. The relationship between interception and water are discussed along with transpiration later in this chapter.

The portion of precipitation not intercepted is delivered to the ground. Once on the ground, precipitation is affected by several processes including surface detention, infiltration, overland flow, subsurface flow, and percolation to ground water. Initially, surface detention is a principal factor in water movement. The amount and duration of surface detention is related to the micro-relief of a site. In a forested environment, micro-relief can result from many factors including woody debris on the ground, "pit mounds" from old windthrow events, animal digging activity, and soil disturbance from timber harvest activity. In a grassland or shrubland environment, grazing can increase micro-relief with hoofprints if grazing intensity is light to moderate, or decrease it if grazing intensity is heavy. In an agricultural environment, micro-relief can result from cultivation activities. When cultivation results in furrows, surface detention has a longer duration when furrows follow land contours.

Subsequent to surface detention is the infiltration process, which results in rain or snowmelt water seeping into the soil. The bulk density porosity, root mass and organic material present in the soil, are the principal factors affecting infiltration. Any activity that tends to compact the soil structure, forms crusts by clogging surface pores, and/or reduces the organic material present will reduce the infiltration rate of the soil. Such activities include: heavy equipment operations with timber harvest or agriculture, and excessive livestock grazing pressure. For a more detailed previous discussion of soil compaction, refer to the discussion about long-term soil productivity in this chapter.

Water that does not infiltrate into the soil and exceeds the capacity of a site's micro-relief for storage, runs downslope into streams as overland flow, which often generates floods. Overland flow is uncommon in the forested environments of the Basin because of the complex vegetation and litter present and the wide distribution of porous soils. A notable exception occurs when organic matter is removed and soils become hydrophobic following intense fires. Overland flow is also relatively uncommon in the grassland and shrubland environments of the Basin for many of the same reasons. Overland flow is a more common process in agricultural environments, especially where annual crops are grown on steep terrain, such as the Palouse. In general, overland flow events are not frequent in the Basin, but they have substantial effects on soils, stream channels, and riparian vegetation when they do occur. Such events can be quite erosive and often deliver considerable sediment to streams and other surface water systems.

Most water reaching the ground surface infiltrates to become soil moisture where it is held by capillary forces until it is accessed by plants or displaced by additional soil water movement. This displacement results in percolation laterally as subsurface flow into streams or vertically into the ground water zone (water table). Major effects on subsurface flows result from road construction on moderate to steep slopes. The cut-and-fill slopes created by roads commonly interrupt and concentrate subsurface flows in the road drainage ditch in all but the most porous subsoils. These

subsurface flows in the drainage ditch are then often delivered either directly to stream channels or drained across the surface as overland flows. This situation can deliver concentrated flows of water, along with sediment from the road surface and cut-slopes, to the stream channel. Such situations are evident in nearly all heavily roaded areas of the Basin. Steepness of the terrain, road density, and age and construction standards of roads, as well as whether Best Management Practices (BMPs) were followed, are the primary factors that determine the frequency and significance of this process.

The principal human activity affecting groundwater in the Basin is irrigation of agricultural lands. This activity has become increasingly common in the past few decades and accounts for substantial groundwater withdrawals in some areas. In other areas, irrigation with surface water from rivers has resulted in the establishment of a new water tables that commonly create areas of surface water in depressions.

Not all infiltrated water percolates into ground water. Instead some remains as soil moisture and either evaporates from the soil surface or is absorbed by plants into tissue or returned to the atmosphere through transpiration (the atmospheric return of water vapor through plant tissue). Because transpiration (much like interception) is a function of vegetation cover, activities that reduce or increase vegetation affect this process. Transpiration is also affected by the photosynthetic activity of the vegetation present; however, for general discussion purposes vegetation cover is primarily emphasized. In a forested environment, tree canopy removal through harvest, fire, insects, and pathogens reduces transpiration; conversely, increasing tree canopy density through fire suppression or reforestation increases transpiration. In grassland or shrubland environments, grazing and fire commonly reduce transpiration, whereas fire suppression with plant succession to increased shrub cover and woodlands increases transpiration. In an agricultural environment, perennial crops, particularly those with complex structure such as orchards, increase transpiration. Annual crops that only occupy the site for part of the year decrease transpiration. The amount of soil moisture transpired by the vegetation on a site influences the amount of water that percolates laterally and vertically into ground water and into stream channels and lakes. Therefore, the amount of transpiration, interception, and other evaporation returns to the atmosphere can increase or decrease water yield and streamflows. This fact is particularly important in evaluating the timing and duration of "spring runoff" peak flows and the volume and duration of "summer" base flows within streams.

Stream channels are the integrated products of the watershed that contains them, or as W. M. Davis (1899) observed "it is like the entire leaf." The ecological processes described above and the hydrologic effects of management activities all influence the pattern and character of rivers and streams. An important characteristic of hydrologic systems is that rivers, hillslopes, and floodplains are all parts of an integrated system. Uplands historically produce runoff and sediment within a certain range of levels. Stream channels, in turn, develop through time to move that range of runoff and sediment through the stream system and into larger streams, lakes, or oceans. Any activity that significantly changes the amount of runoff or sediment produced will result in stream channel changes. Large scale disturbances such as landslides and major floods do occur in the Basin and are important factors influencing watershed processes, however, the relatively smaller scale (yet widely distributed) changes in runoff and sediment following management activities are commonly the primary disturbance agents that influence the hydrologic integrity of aquatic systems within the Basin.

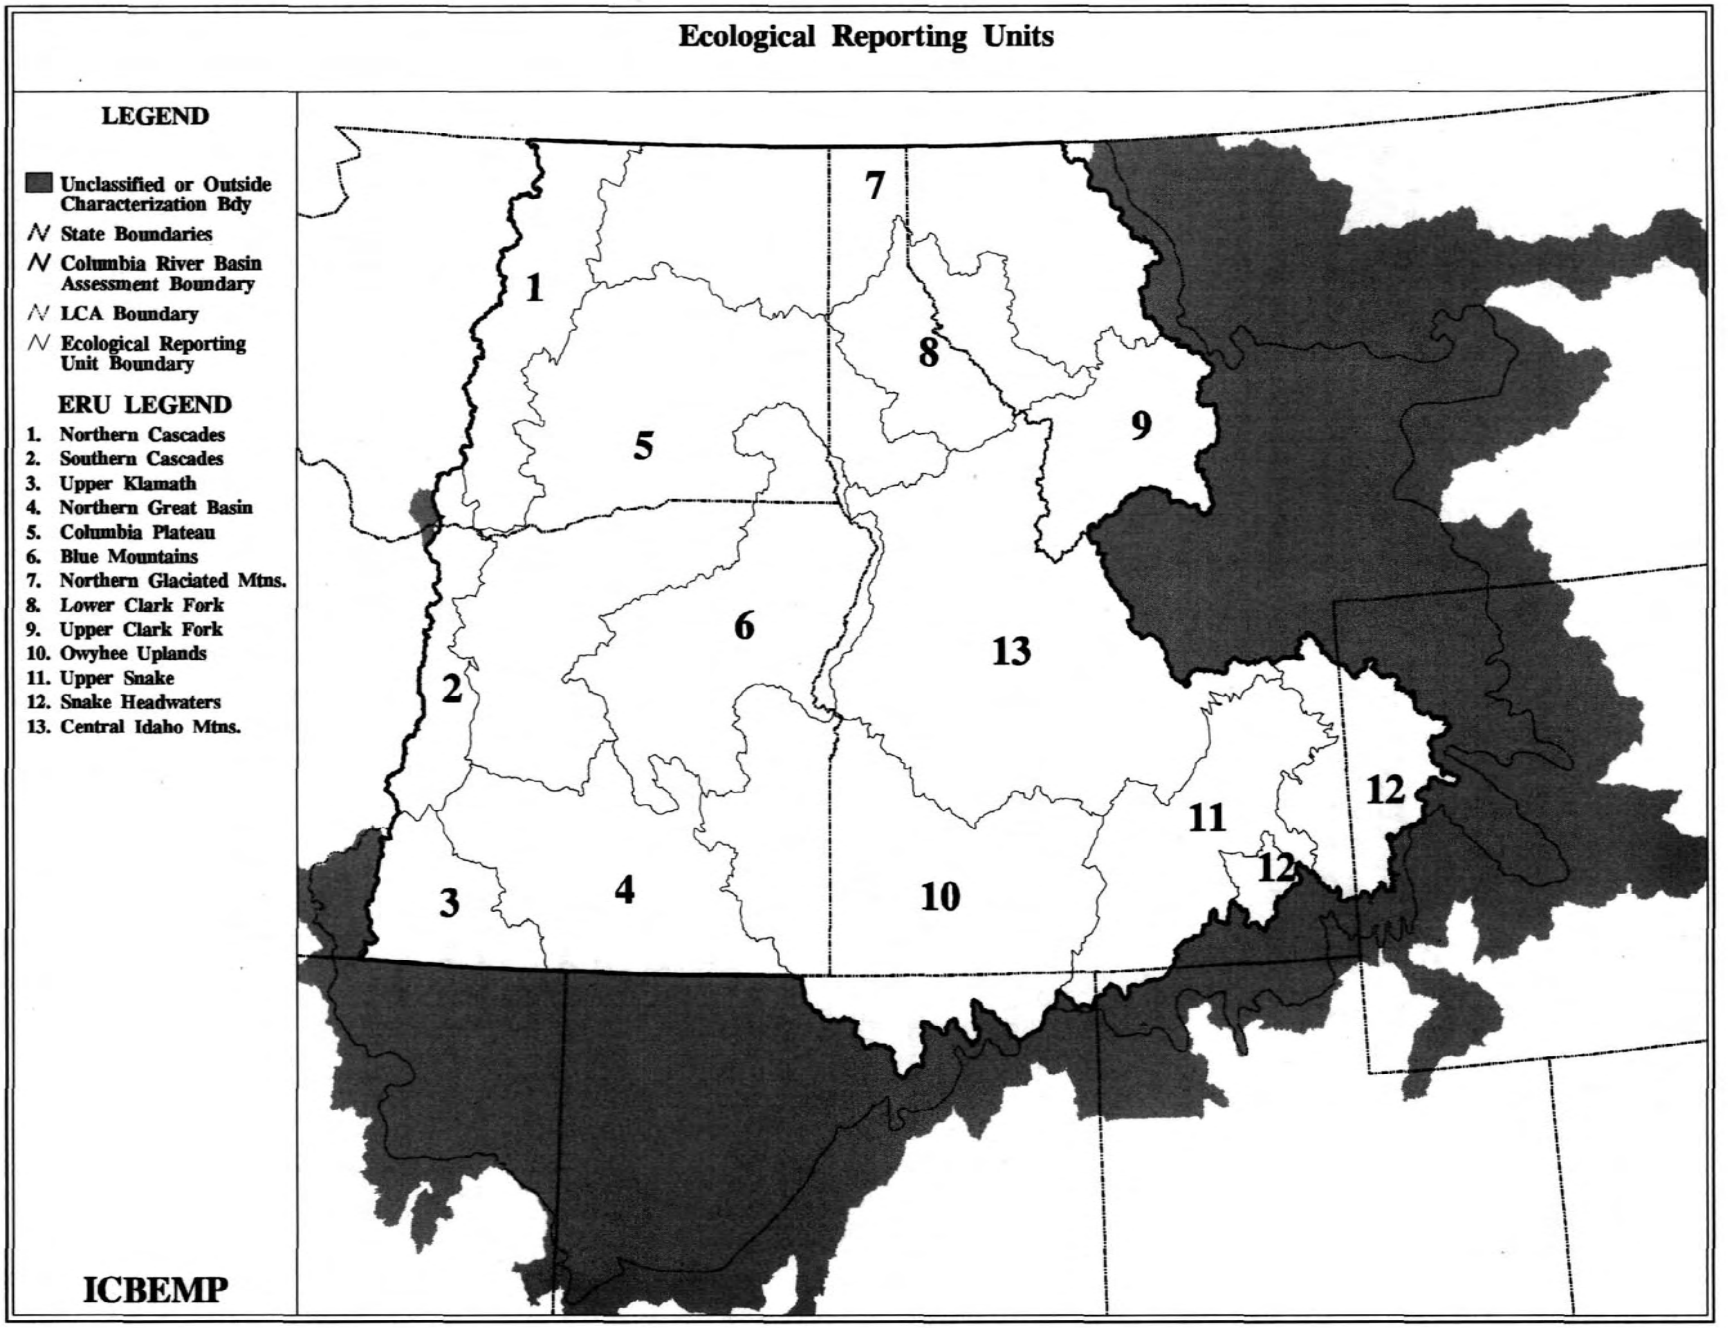
SUMMARY CHARACTERIZATION OF CLIMATE, GEOLOGY, SOILS, AND HYDROLOGY INFORMATION BY ERU

The following discussion presents an overview of the major climate, geology, soils, and hydrologic patterns and processes within each ERU of the Basin (map 2.32).

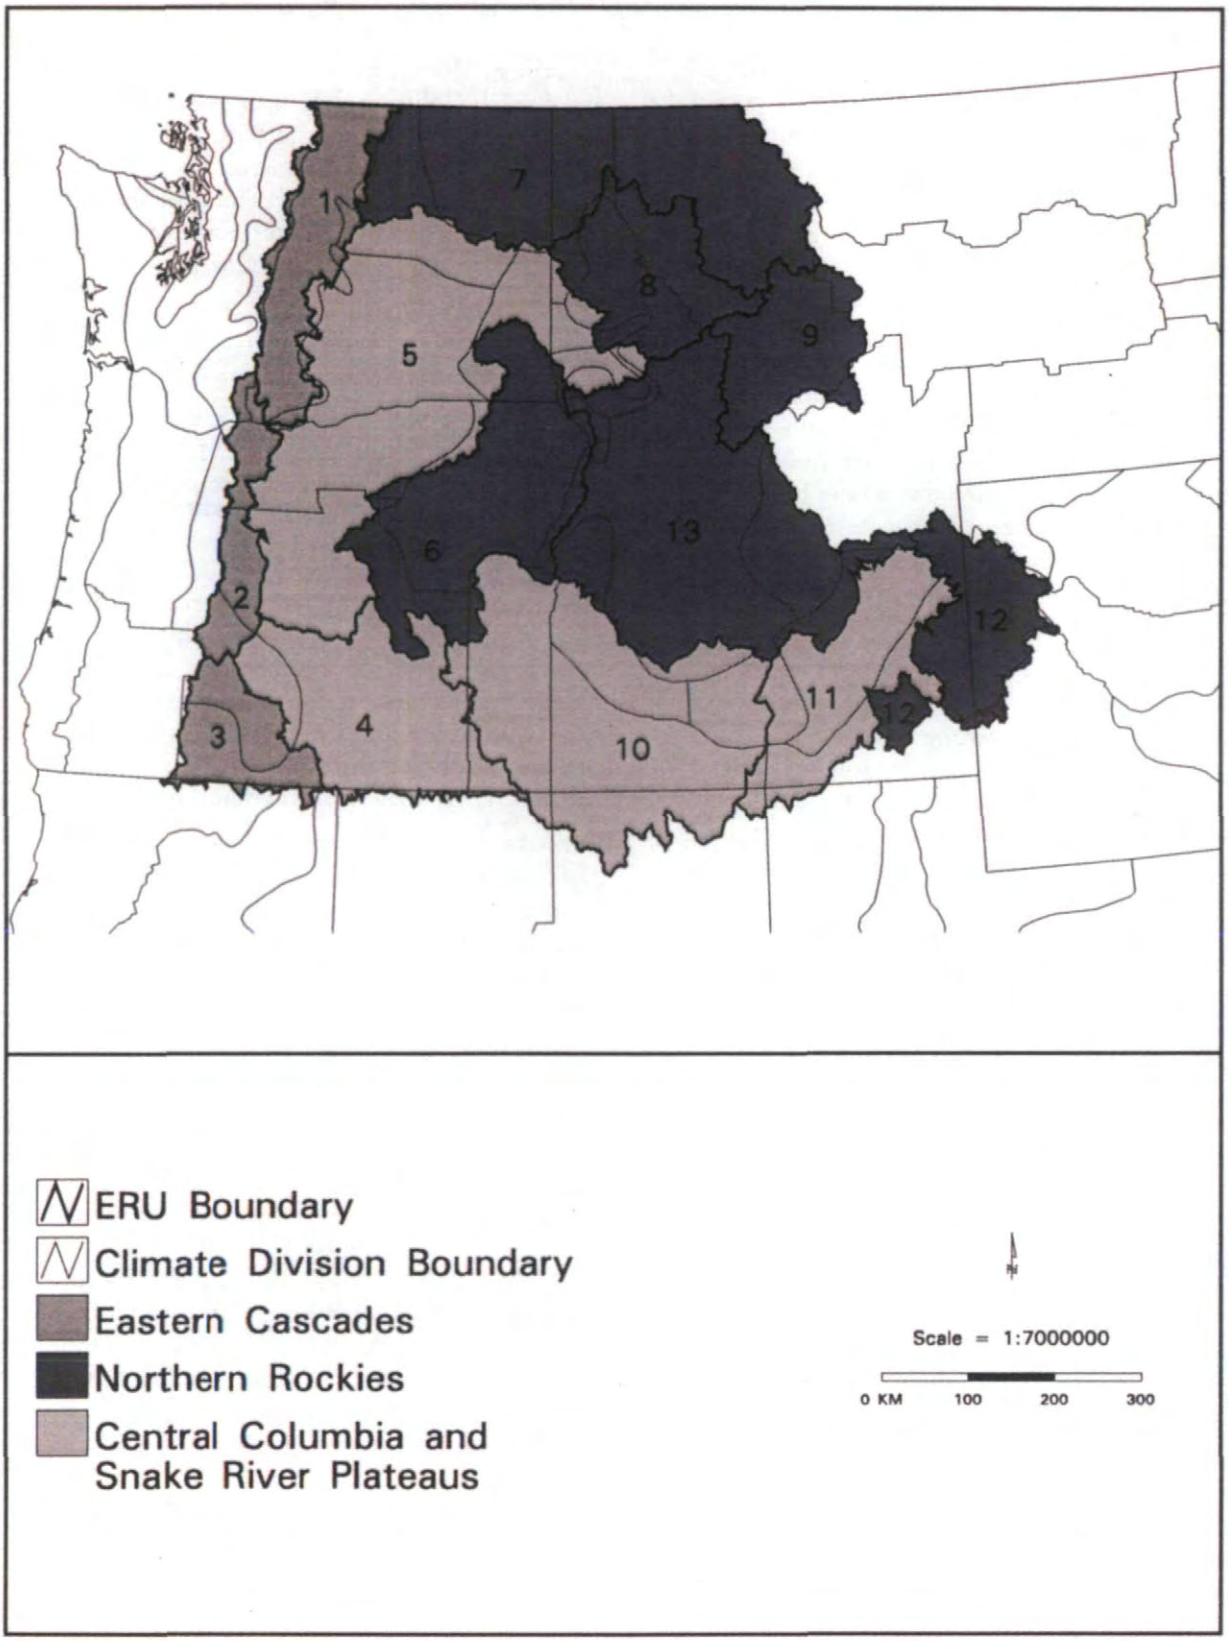
Climatic summaries are presented first, by three regional scale groupings of ERUs (map 2.33):

- Eastern Cascades
- Northern Rockies
- Central Columbian and Snake River Plateau

A generalized description of the biophysical environment relations within each ERU is also presented which provides the following information:



- Key statistics about characteristic subsection, lithology, potential vegetation type composition, and basic climatic and morphometric descriptions.
- Key descriptions of generalized soil characteristics and evaluation of productivity.
- Key interpretations of stream type groups, valley bottom settings, and wetland complexes.
- Key interpretations of upland erosion processes and sediment sources.
- Key interpretations of the predicted vulnerability of stream channels to disturbances, inherent channel recovery potential, and sensitivity to disturbance of the subwatersheds within each ERU.



Climate Overview

The Basin is in a transition-type climate zone and is influenced by three distinct air masses:

- Moist, marine air from the west that moderates seasonal temperatures.
- Continental air from the east and south, which is dry and cold in winter and hot with convective precipitation and lightning in summer.
- Dry Arctic air from the north that brings cold air to the Basin in winter and helps cool the Basin in summer.

Map 2.32—Ecological Reporting Units.

Map 2.33—Basin's climate by three broad regions.

Eastern Cascades—The Cascade Mountains block most marine air from entering the Basin. The eastern slopes of the mountains (ERUs 1, 2, and 3) lie in a rain shadow of oncoming Pacific storms. During winter, however, when westerly winds are strongest, enough moisture spills over the crest to cause this region to remain wetter than other parts of the Basin (map 2.27). This region also receives high quantities of snowfall. Seasonal totals of snowfall typically range from about 200 centimeters in the south (ERU 3) to over 300 centimeters in the north (ERU 1), with greater amounts at higher elevations (over 2,000 cm of snowfall has been recorded at Crater Lake, Oregon). During summer, when westerly winds are weak, the rain shadow effect of the Cascades is most apparent and this region becomes the driest in the Basin (map 2.27).

Chinook winds can cause occasional warm, dry, and windy conditions that rapidly melt snow or initiate blow-down. Strong winds are also common within mountain gaps as air flow is channeled from both east and west directions. The westerly gap winds, most common in summer, are strongest as they flow into the Eastern Cascade region. The principal mountain gap is the Columbia River Gorge, just east of Portland, Oregon. Tornadoes and funnel clouds have been observed near the outflow of the gorge's westerly winds. In addition, the persistence such winds allows the gorge to be one of the nation's principal wind-surfing recreation areas. Strong southerly winds are also common, mainly during winter, on several east-west oriented ridges that protrude into the Basin from the Cascade crest.

Although this region often is under continental-type climate conditions (with cool, dry winters and hot, dry summers), marine air spilling over the mountain crests and through mountain gaps moderates both summer and winter temperatures. In addition, Arctic air often pools in the Basin and is pulled against the Cascades, causing a persistent temperature inversion to about 1,200 meters, especially in winter. Sharp contrasts in temperature occur when Arctic air is displaced by marine air; rain-on-snow flooding is common at all elevations.

Northern Rockies—The Canadian Rockies and British Columbia Mountains block most Arctic air from entering the Basin. The deep Okanogan, Columbia, and Pend Oreille valleys, however, can funnel the dry Arctic air into the Basin where it often stagnates, especially during winter when the air is cold and dense.

The Rocky Mountains on the eastern border of the Basin intercept continental air masses that rise over the mountains resulting in thunderstorm development around the edge of the Basin, especially in western Montana and southern Idaho. A thermal trough that migrates northward during spring and summer can also cause thunderstorms, mainly in central Oregon around the Blue Mountains (ERU 6). The convection causes an increase in precipitation during spring, with 24-hour accumulations often greater than 25 millimeters. Drier lightning is more common during summer and fall. Most convection and lightning occurs in the east and southeast units of this region (ERUs 9 and 12), nearest the Continental Divide.

Blow-down in this region is common. Strong down-burst winds associated with convective cells can cause blow-down, most commonly during spring. Blow-down also occurs in the north-south elongated valleys that channel strong southerly storm winds, mainly during winter. The high and contrasting topography also favors accelerated storm winds near ridgetops during winter and persistent slope winds during summer.

The northern Rockies are the coldest part of the Basin with mean winter temperatures between minus 4.2° C and minus 10.2° C. Snowfall amounts vary from about 200 centimeters to over 300 centimeters, with greater amounts at higher elevations. Although winter precipitation in the northern Rockies is less than the eastern Cascades, snowfall amounts are comparable for two reasons:

- Cold winter temperatures cause relatively low density snowfall in the northern Rockies, so snowfall amounts appear greater even though snow water equivalents may be less than the eastern Cascades.
- Colder spring and fall temperatures in the northern Rockies allow more snowfall during these two seasons than in the warmer Cascades.

Despite cold winter temperatures in the northern Rockies, occasional marine intrusions can cause sudden warming and initiate rain-on-snow floods, mainly at lower elevations and those places exposed to flow from the Columbia Gorge. In summer, the marine intrusions moderate summer high temperatures and add moisture to the convective cycle, increasing the chance that lightning is accompanied by precipitation.

Central Columbia and Snake River Plateaus—This is the driest part of the Basin (map 2.27). The Columbia Plateau and Snake River Valley, however, are susceptible to marine intrusions that can relieve summer hot spells and winter cold spells. The accompanying moisture can extinguish summer wildfires or cause winter rain-on-snow floods. Although rain-on-snow floods are rare in this region, any occurrences are more destructive and of much greater magnitude than spring floods. Typical seasonal snowfall totals range from 40 to 80 centimeters.

The upper plateaus (ERUs 4, 10, and 11) experience a moderate spring cycle of convective precipitation with lightning most common in ERU 11. Convection can be caused by the northward migration of a thermal low, especially in ERUs 4 and 5, and in the western part of ERU 10. Also, hot unstable air from the Great Salt Lake region can increase thunderstorm and lightning development over ERU 11 and eastern ERU 10.

Strongest winds in this region occur during the summer from the west at the east outflow of the Columbia Gorge (ERU 5) and during the winter from the south and west along ridgetops. Although climate in this region is marked by few extremes, long periods of stagnation occur during winter in the central Columbia Basin (ERU 5), in the Snake River Valley (ERU 10), and in high isolated basins (ERUs 4, 10, and 11). The stagnation events cause this region to be the most susceptible to air pollution concerns.

Climate trends in ERUs—Because ERUs do not exactly match the National Weather Service climate division boundaries used to calculate 30-year averages, new summaries were calculated using available COOP and HCN data within each ERU (tables 2.21, 2.22a and 2.22b). To analyze climatic trends in each ERU of the Interior Columbia River Basin, representative stations were selected that had weather records extending back more than 40 years and occurred near the mid-range of station elevations within a unit. A simple 10-year moving average of monthly mean values was used to evaluate trends and to help approximate year-to-year variability. Although historical trends in precipitation were apparent, trends in temperature were not obvious.

A notable maximum in snowfall and winter precipitation occurred in all areas during the mid-1970s. This event coincided with a stepwise change in other climate variables during 1976 (Ebbesmeyer and others 1991).

Winter precipitation since the mid-1970s decreased by 30 to 80 percent in all areas to a level comparable to historical means, except in ERUs 3, 8, 9, and 10, where the current winter precipitation trend is slightly lower than any in previous history.

Table 2.21—Dataset descriptions for climate data used in the Basin assessment.

Dataset Name	Begin Year	Basin Sites	Time Step	Duration	Measurement
HCN	1895	9	daily	annual	T, ppt
Coop	varies >1895	>300	daily	annual	T, ppt
SNOTEL	1978	45	daily	annual	T, ppt, SWE
Snow Course	1930	50	monthly	winter	H, SWE
RAWS	1985	~200	hourly	summer	T, Tf, RH, ppt, W
SAMSON	1961	10	hourly	annual	T, Td, RH, W, P, Q
RAOBS	1948	2	2/day	annual	T, Td, W, P (multiple heights)

In contrast to winter trends, all areas showed an increasing trend (30 to 80%) in summer precipitation during the last 30 years. Comparable highs in summer precipitation occurred around 1910. Since the mid-1980s, about half the Basin (ERUs 3, 6, 10, 12, and 13) has shown a 20 to 70 percent decrease in summer precipitation, but remains 40 to 80 percent above the 1960 levels. Periods of drought throughout the Basin since 1988 appear to be related to the overall decrease in winter precipitation and beginning signs of decreasing summer precipitation.

Trends in annual precipitation over the last 100 years show significant variability around the Basin (Karl and others 1996). The central Basin (Washington, northeastern Oregon, and eastern Idaho) showed 5 to 10 percent increases. Elsewhere, annual precipitation decreased 5 to 10 percent, with ERU 3 showing a 20 percent decrease. It is difficult to compare the 100-year trends with those calculated from stations within each ERU that have records of only 50 to 70 years. Also, Mock (in press) illustrated the highly seasonal nature of precipitation in the western United States. Therefore, changes in spring and autumn months that influence annual trends are not shown in the January and July records analyzed for each ERU.

Although there has been almost no change in measured winter temperatures in the Eastern Cascades, this area has had a notable increase in the percentage of winter precipitation. This increase could indicate somewhat higher snow levels with less snow accumulating at lower elevations. In the same region, a 1° to 2° Celsius decrease in the diurnal range of summer temperatures may suggest slightly increasing summer cloudiness. Other regions have less obvious changes, but overall trends appear to be toward slightly cooler summers and slightly warmer winters.

Mean temperature has increased 1° to 2° Celsius throughout the Basin over the last 100 years (Karl and others 1990). Because many of the stations used to analyze ERU trends have records since the 1930s drought era, their trends are smaller than the 100-year trends and even slightly negative.

The persistent drought throughout the Basin in the 1930s may relate to warm winter temperatures and associated high snow levels. Many areas also experienced a decrease in summer precipitation during the 1930s, adding to severe drought conditions. Periods of significant drought in a few areas of the central Basin and plateau regions during the 1950s appear driven more by warmer than normal temperatures rather than changes in precipitation.

Table 2.22a—Climate Summary for each Ecological Reporting Unit (ERU) with number of weather stations. The range of station elevations (meters) are shown. Data from available HCN and COOP weather observation stations having records of 10 years or more were used to calculate monthly mean values (°C) of maximum daily temperature [T(max)], minimum daily temperature, daily range in temperature [del T], average daily temperature [T(avg)], and monthly total values of daily precipitation [PPT] in millimeters and snowfall in centimeters. In addition, the ratio of snowfall to precipitation [%Water] is given to help show water content of snow.

Ecological Reporting Unit Descriptions

ERU 1: Northern Cascades

Two subsection groups dominate this ERU:

- M242-01, characterized by glaciated mountains and foothills of igneous and sedimentary rocks that have been modified by glacial and fluvial processes.
- M242-05, characterized by mountains and foothills covered by ash and pumice, frequently underlain by igneous extrusive rocks, and modified by fluvial, mass wasting, and aeolian processes.

This area has cold stony soils including some with higher amounts of organic matter. Southern Washington has some soils with thick volcanic ash, and other soils with thick dark topsoils. Due to rain shadow presence, soils on the eastslope are usually dry for a significant time during the summer. Many of these soils are influenced by volcanic ash and commonly have low bulk density, topsoils rich with organic matter, and subsoils with accumulated clay.

High Elevation Sites—This portion of the Northern Cascades has shallow to moderately deep, cold soils with low available nitrogen. These limitations produce low productivity sites. Soils are generally resilient and have low to moderate susceptibility to compaction. Natural surface erosion and mass failure hazards are high.

Mid- to Low-Elevation Sites—This portion of the Northern Cascades is highly productive. Many soils in this area have formed in deep, volcanic ash or on landflows with abundant moisture. Soils on steep slopes are shallow to moderately deep with limited moisture and nutrient content. Organic matter and moisture are the most limiting factors to productivity in this area. The soils present are generally resilient but moderately susceptible to compaction. Natural surface erosion and mass failure hazards are moderately high.

The Northern Cascades ERU has one of the lowest average elevations (approx. 1,200 m) within the Basin. The average slope is 27%, which is similar to ERUs 8 and 13. Annual precipitation is 95 cm which is similar to ERUs 2 and 8. The major potential vegetation types are cool moist (F22); cold moist (F12); and warm dry forestlands (F33), with each having constancy and average percent cover values, when present, of greater than 55 percent and 15 percent, respectively.

The dominant valley settings in the Northern Cascades are those with steeply sloping, moderately to highly confined valley bottoms (VB forms 1 and 2), and those having gentle slopes with low confinement (VB form 9), with constancy and average percent composition values greater than 55 percent and 20 percent, respectively. Rosgen A stream types, that are characterized by cascades and step-pool systems, dominate this ERU (88% constancy and 72% average percent composition when present); however, rapids-dominated B-stream types are also very common (as determined in subwatershed subsampling). Other locally important stream types that are potential sources of sediment in this ERU are braided system D-types (about 40% constancy, but having low average percent composition values).

The value for erosion, assuming existing vegetation, is in the 65th percentile. Only three other ERUs have similar median values (ERUs 5, 6, and 7). The estimated median mass wasting index is at the 81st percentile; this high potential is corroborated by the stream type group estimates. The potential for sediment to reach streams is also high with a median sediment delivery hazard of about 78 percent, the highest across all ERUs.

The median index value for stream channel sensitivity to increased flow and sediment, at a site, is the lowest of all ERUs. There are, however, numerous outliers between the 40th and 80th percentile, which indicates that other localized sensitivity levels occur. The downstream transfer effects of increases in flow and sediment are average as contrasted across all ERUs. Vegetation is relatively unimportant for maintaining the mor-

phology of the A-, B-, and D-stream types present. Overall, the potential for the estimated dominant stream types of this ERU to recover from disturbance is among the highest of all ERUs.

ERU 2: Southern Cascades

Three subsection groups dominate this ERU:

- M242-05, characterized by mountains and foothills covered by ash and pumice, frequently underlain by igneous extrusive rocks, and modified by fluvial, mass wasting, and aeolian processes.
- M242-01, characterized by glaciated mountains and foothills of igneous and sedimentary rocks that have been modified by glacial and fluvial processes.
- M342-07, characterized by foothills composed mainly of loess over basalt that has been modified by fluvial and aeolian processes.

Constancy values for these subsection groups are 74 percent, 56 percent, and 29 percent, respectively. Average percent composition of these types, when present, varies from 49 percent to 59 percent. The lithologic mosaic for this ERU is dominated by mafic volcanic flows (98% constancy, and almost 50% average composition), and calcic-alkaline volcanoclastics (61% constancy, and about 25% average composition).

Cold stony soils dominate this ERU. Due to the rain shadow presence, east slope soils are usually dry for a significant time during the summer. Many of these soils are influenced by volcanic ash, and have low bulk density, high organic matter, and subsoils with accumulated clay. The southern part of this ERU has cold soils formed in volcanic ash and pumice from Mount Mazama.

Productivity limitations of soils include cold temperatures, short growing seasons, and limited available nitrogen or other nutrients. Natural mass failure hazard is low, and natural surface erosion hazard is moderately low.

The Southern Cascades ERU has one of the highest annual precipitations (100 cm) and is also in the highest class for maximum winter temperature (along with ERUs 5 and 10).

The major potential vegetation types present are warm dry (F33); cool moist (F22); and cool, very dry forestlands (F24). Each of these forestland types have constancy values greater than 59 percent, and average compositions of greater than 20 percent.

The dominant valley bottom settings present have steep slopes with low to moderate confinement (VB 2), moderate slopes with moderate confinement (VB 5), and gentle slopes with low confinement (VB 9). Steep A-stream types, characterized by cascades and step-pool systems predominate, followed by the more stable, rapids-dominated B-stream types. There are also significant numbers of E-stream type reaches in this ERU, which are characterized by narrow, torturously meandering channels, and frequently cool, swift water. Wetlands and lakes were estimated to be present in roughly 30 percent and 50 percent, respectively, of the valley bottoms described in subsampling.

The median value for the erosion, assuming existing vegetation cover, is about the 45th percentile, which is similar to that of ERUs 8, 9, 12, and 13. The value for mass wasting is about the 81st percentile, which is similar to the Northern Cascades. The spread of the mass wasting index values in this ERU, however, is much greater, reflecting the relatively greater number of gently sloping valleys present. The sediment delivery hazard of this ERU is in the mid-range (about the 38th percentile) of all ERUs.

The median index value for stream channel sensitivity to increases in flow and sediment is low (about the 20th percentile), but the spread in this index value is large, possibly reflecting the mosaic of E-types and the unstable, entrenched F- and G-stream types present. Overall, the downstream transfer effect of increases in flow and sediment is low, but there are several high outliers. The median value for potential bank erosion is moderate (about the 38th percentile), but there is a large

spread in related index values. The importance of vegetation to maintaining the morphology of the dominant channel types of this ERU is average (about the 48th percentile). The median recovery potential is high (about the 80th percentile), reflecting the estimated high percentage of A-, B-, and C-stream types present. The spread in this index is large, however, which reflects the poorer recovery potential of the F- and G-stream types also described in subsampling.

ERU 3: Upper Klamath

Three subsection groups dominate this ERU:

- M261-02, characterized by intermontane basins, foothills, and plateaus of igneous extrusive rocks overlain by ash, pumice, and alluvium that have been modified by fluvial and volcanic processes.
- M242-02 characterized by plains of ash and pumice over volcanic rocks, mostly basalt, that have been modified by alluvial and volcanic processes.
- M261-04, characterized by mountains comprised of extrusive igneous rocks, modified by fluvial processes.

Percent constancy values for each subsection group vary between 42 percent and 47 percent, and average percent composition, when present, varies from 55 percent to 71 percent. In addition, lake sediments and playas, and alluvium are important lithologic components in some areas (60% and 42% constancy values, respectively).

The Upper Klamath ERU has cold dry soils on pumice-mantled plateaus, and mountains. Soils on pumice plateaus have light-colored surface layers and little horizonation, and can have some volcanic ash influence. Soils that occur on high plateaus and mountains generally have dark-colored organic matter-rich surface layers, with some volcanic ash. There are some wet, cool and cold soils in basins and valleys. (Some of these consist of mineral soils and others are organic soils.) There are dry warm soils on floodplains and terraces and on grass-shrublands. The soils that occur on floodplains and terraces have some dark-colored surface layers rich in organic matter and some wet soils with dense restrictive layers. Soils on grass-shrublands are generally shallow with dark-colored organic matter-rich surface layers, and subsoil accumulation of clay.

Productivity of soils in the Upper Klamath is relatively low. Major limitations to plant growth in this area include cold and dry soil conditions, and inadequate amounts of organic matter and available nitrogen. The resiliency of these soils is generally low, often making them susceptible to compaction. Natural mass failure hazard is low, and natural surface erosion hazard is moderately low.

This ERU has a high average elevation (1,560 m), and has some of the lowest relative relief and lowest average slopes (10%) of all ERUs. It has the 5th lowest annual precipitation value of the ERUs (57 cm), and is in the highest class of winter solar radiation (0.0047 joule/m^2). The major potential vegetation types of this ERU are warm dry (F34); hot moist (42); and hot, very dry forestlands (F44); each type has constancy values of 62 percent or greater. Cool, very dry forestlands (F24) are also common (42% constancy) and, where present, have high average composition (48%).

The dominant valley bottom settings of this ERU are those having gentle valley slopes and moderate to unconfined side-slopes (VB forms 8 and 9); such valleys occur in all subwatersheds, with average composition values of 17 percent to 38 percent. Steep, confined valley bottoms and moderately steep, moderately confined valleys are also common in most subwatersheds, but have lower average composition values. Steep, step-pool, A-stream types are common, and the majority of these types are estimated to be unstable channels (that is, they generally contain finer bed materials). Rapids-dominated B-stream types are also common. Compared to all ERUs, the Upper Klamath ERU has a high percentage of narrow, highly sinuous E-stream types (50% constancy

across subwatersheds with 10% average composition). This ERU also has a high percentage of channelized reaches (50% constancy), entrenched, low-gradient F-stream types (50% constancy), and a moderate percentage of entrenched, gully G-stream types.

The Upper Klamath ERU (along with ERU 4) is within the lowest class across all ERUs for estimated upland erosion, given existing vegetation. It is within the second lowest class for mass wasting hazard (median value is the 60th percentile), and has the lowest ranked sediment delivery hazard across all ERUs. This ERU ranks second highest across all ERUs in terms of the sensitivity of stream channels at-a-site to increases in flow and sediment (median value is about the 70th percentile). It is in the second lowest class (along with ERUs 7 and 12) with respect to downstream transfer effects of increased flow and sediment. Only about 30 percent of the ERUs within the Basin are ranked higher with respect to potential for bank erosion, reflecting the occurrence of sensitive E-types, and unstable F- and G-stream types present. Riparian vegetation is fairly important to maintaining existing channel morphology in this ERU (median value is about the 60th percentile). This ERU is ranked at the 40th percentile for inherent channel recovery potential, due to the slow recovery times of the unstable A-, F-, and G-stream types present.

ERU 4: Northern Great Basin

Three subsection groups dominate this ERU:

- 342-05, characterized by plateaus and foothills composed mainly of tuffs and basalts that have been modified by fluvial and aeolian processes.
- 342-04, characterized by intermontane basins and valleys composed mainly of alluvium, ash, and lacustrine materials over basalt.
- 342-06 characterized by mountains composed mainly of tuffs and basalts that have been modified by fluvial processes.

Lake sediments and playas, and alluvium are present in 75 percent and 48 percent of the subwatersheds, respectively, with average composition values of 13 percent and 20 percent, where present.

The soils generally have light-colored surface layers. The soil horizons may be the result of movement and accumulation of salts, carbonates or silicate clays, or of cementation by carbonates or silica. These are generally dry soils with cool to warm temperatures. Large areas have saline-sodic soils.

In the northern Great Basin, moisture is the principal limiting factor to plant growth. Riparian areas and higher elevation sites, however, are wetter and have the most organic matter. They are, therefore, generally the most productive. Low elevation sites with the least precipitation and areas of saline-sodic soils are the least productive settings in this ERU. Resiliency of these soils is generally low, often making them susceptible to compaction. Natural mass failure hazard is low, and the natural surface erosion hazard is moderate to high.

The Northern Great Basin ERU occurs at higher elevations (average is approximately 1,600 m), and is within the lowest class of relative relief across all ERUs. It has the lowest average slopes across all ERUs (9%), but there are numerous outliers representing localized steep slopes. It is in the lowest class of annual precipitation (comparable to ERUs 5 and 10), and is in the second highest class of winter solar radiation (0.0046 joule/m^2). The major potential vegetation type of this ERU is warm dry shrublands (S33) having a constancy value of 88 percent, and average composition of 70 percent, where present.

ERU 5: Columbia Plateau

Five subsection groups dominate this ERU:

- 342-07, characterized by foothills composed mainly of loess over basalt that has been modified by fluvial and aeolian processes.

- 342-03, characterized by plateaus and high plains of fluvial and lacustrine sediments and ash deposits created by aeolian, fluvial, and lacustrine processes.
- 331-02, characterized by intermontane basins and valleys of valley fill, alluvium, and lacustrine materials overlying volcanic and sedimentary rocks.
- 331-04, characterized by glaciated mountains of volcanic and sedimentary rocks that have been modified by colluvial, fluvial, residual, and glacial processes.
- 342-05, characterized by plateaus and foothills composed mainly of tuffs and basalts that have been modified by fluvial and aeolian processes.

Mafic volcanic flows occur on 88 percent of the subwatersheds within this ERU, with average composition values (where present) of 47 percent. Loess deposits occur on 48 percent of all subwatersheds within the ERU, with an average composition, where present, of greater than 50 percent.

Columbia Basin Section and west half of Palouse Prairie Section—The soils are mostly warm and dry. They formed in parent materials resulting from erosion and redeposition by great floods and strong winds across the relatively level lava plateau. Volcanic ash deposited in this area has been mostly eroded and mixed with other materials. Loess blankets most of the area. The central part has soils formed in silty and sandy wind-deposited materials. The northeastern part has loess hills dissected by channeled scablands. Soils on the loess hills formed in mostly deep, coarse-textured loess; some have dark topsoil; some have lime-enriched subsoil; and some have clay-enriched subsoil. Soils on the flood-scoured channeled scablands are similar to soils on the highly dissected lava benches in the western part of the Section. In the south, the soils are moist except in summer and commonly have dark, organic matter-rich topsoil; some are shallow to bedrock; some have lime and commonly have dark, organic matter-rich topsoil; some are shallow to bedrock; some have lime-enriched and clay-enriched subsoils, and some have thick dark topsoil. Volcanic ash influence is recognized in some soils.

High Lava Plain Section—The soils are generally warm and dry, varying in depth to bedrock and influence of volcanic ash. The southern part has some soils with thin dark topsoils and some with volcanic ash. Other soils have thin dark topsoil and a cemented hardpan that impedes roots, and a clay enriched subsoil, with or without volcanic ash. Shallow sandy soils also occur in this area. In other areas, most soils have thick dark topsoil and clay-enriched subsoil. Some of these soils also contain volcanic glass.

The southern portion of the Columbia Plateau has predominantly moderate to low productivity soils that support grasses, forbs, shrub communities, and juniper woodlands. The most productive soils of this area are located in riparian settings. Where soils are deep and moisture is available, productivity is commonly moderate. Shallow droughty soils, however, dominate this area with moisture as the principal limiting factor to plant growth. Surface organic matter content of these shallow soils is low, and they are generally resilient but susceptible to compaction. Natural mass failure hazard in this area is low. Although soils on slopes steeper than 40 percent are highly erodible, gentle slopes generally have moderate to low erosion hazards.

The northern portion of the Columbia Plateau ranges from scablands, with shallow droughty soils with reduced water-holding capacity and low productivity, to deep loess-influenced soils with high productivity. Loess soils are highly susceptible to wind and water erosion. Sandy glacial soils occur in some areas and are droughty, have low productivity, and moderate to high erosion hazards. The major limitation to plant growth is moisture with shallow soil depth being an additional problem to management in the scablands. Soils are generally not resilient or susceptible to compaction in this area. Although natural mass failure hazard is low, the surface erosion hazard is high.

The Columbia Plateau ERU has the lowest average elevation across all ERUs (approx. 500 m), and is within the lowest class of relative relief and lowest average slope (median slope value is about 8%, but numerous outliers indicate localized high slopes). Along with ERUs 4, 5, 10, and 11, this ERU is in the lowest annual precipitation class (40 cm). This ERU is tied with ERU 2 for the highest average value for maximum winter temperature (about 4.5° C), and is within the highest class of average August temperature (18° C). The dominant potential vegetation types of this ERU are warm dry shrublands (S33); warm, dry herbaceous lands (H33); and cool moist shrublands (S22).

The dominant valley bottom settings are highly confined with steep valley slopes (VB 1); moderately confined with moderate valley slopes (VB 5); and moderately confined with gentle slopes (VB 8). A-stream types, characterized by step-pools, are dominant, and about two-thirds of these are estimated to be unstable and thus high sources of sediment. Also common in this ERU are B-stream types (characterized by rapids), and C-stream types (that is, alluvial channels that are well-connected to their floodplain processes). This ERU has a high number of braided, D-stream types (constancy value is 62%), but their occurrence is localized. It also has a high number of unstable, entrenched F-types (34% constancy with 11% average composition), as well as a large proportion of channelized reaches (comparable in extent only to ERU 11).

The erosion index of this ERU, assuming current vegetation, is at the 70th percentile of all ERUs (which is similar to ERUs 5, 6, and 7). The mass wasting hazard index is the third lowest across all ERUs, reflecting the generally gentle slopes and low precipitation present. The sediment delivery hazard is about average (48th percentile) as contrasted across all ERUs.

The median index value for at-a-site channel sensitivity in this ERU to increases in flow and sediment is the second highest of all ERUs, but has many lower outliers. In addition, the median index value for bank erosion and downstream transfer effects is the second highest across all ERUs, reflecting the large proportion of unstable, entrenched F- and G-stream types, and braided D-stream types present. The importance of vegetation for maintaining the width to depth ratio of the dominant channels in this ERU is at the 58th percentile across all ERUs, but there is a wide spread in this index value. The recovery potential of streams in this ERU is low, which reflects the unstable A-, F-, and D-stream types present.

ERU 6: Blue Mountains

Three subsection groups dominate this ERU:

- M332-08, characterized by a heterogeneous mosaic of mountains comprised of igneous, sedimentary, and metamorphic rock that have been primarily modified by fluvial and colluvial processes, and secondarily by glaciation, frost churning, and mass wasting.
- M332-07, characterized by a heterogeneous mosaic of mountains comprised of igneous and metamorphic rocks with lesser amounts of sedimentary rocks, all of which have been modified by fluvial, colluvial, mass wasting, frost churning, and glacial processes.
- M332-02, characterized by foothills of granitics and volcanics, with some metamorphic and sedimentary inclusions, all of which have been modified by glacial, fluvial, and residual processes.

Most soils are influenced by volcanic ash from Mount Mazama. The ash mantle is relatively undisturbed on gentle north slopes under forest canopy. On southerly exposures, it has been mostly removed by erosion. Commonly the ash is redeposited and mixed with loess, colluvium, and alluvium. The high mountains have cold, usually moist soils with high amounts of volcanic ash. Some soils have dark-colored surface layers rich in organic matter and some have clay-enriched subsoils; wet meadows have soils with a high water table and an organic surface layer. The lower elevations have cool, usually moist soils with a thick ash mantle and clay-enriched subsoil.

On lower mountain slopes, soils are dry in late summer. Some soils have relatively high amounts of volcanic ash with a surface layer rich in organic matter or with a clay-enriched subsoil. Others have medium amounts of ash and a surface layer rich in organic matter. Some soils with little volcanic ash have surface layers rich in organic matter and may or may not have clay-enriched subsoils. On valley floors, soils under a grass-shrub vegetation are dry for most of the summer and have topsoils rich in organic matter.

In the Blue Mountains, the most productive soils occur at mid-elevations and have thick volcanic ash surface layers. Soils derived from glacial materials at high elevations have moderate to low productivity and are limited by nutrients and cold temperatures. Soils at low elevations and on south slopes with minimal volcanic ash have moderate to low productivity. Although soils are generally resilient in this area, they are highly susceptible to compaction. Natural mass failure hazard is low, and natural surface erosion hazard is moderate.

The Blue Mountains ERU falls within the mid-range class for most climatic and elevational data, with a few important exceptions: it is within the lowest annual precipitation class (however, outlier values reflect the orographic effect of the high peaks present). In addition, this ERU is in the second highest class across all ERUs for both winter solar radiation and average maximum winter temperature (again, there are numerous outliers reflecting localized high elevation settings). The major potential vegetation types are warm, dry forestlands (F33).

The dominant valley settings of this ERU are highly confined, with steep valley slopes (VB 1), moderately confined on moderate valley slopes (VB 5), and moderately confined on gentle valley slopes. The high-gradient, A-stream types present occur on 86 percent of all subwatersheds, with an average composition of 57 percent where present; mid-gradient B-types occur on 74 percent of all subwatersheds, with 23 percent average composition. The low-gradient streams present (C-, D-, and E-types) are estimated to have moderate distribution across all subwatersheds (for example, from about 30% to 48% constancy values). Relative to all ERUs, however, there is a high proportion of unstable, entrenched F-types (present in 30% of all subwatersheds), with an average composition of 18 percent where present.

The value for erosion, assuming existing vegetation, is about the 65th percentile, placing it in the highest erosion category along with the Northern Cascades, Columbia Plateau, Northern Glaciated Mountains, and Upper Snake ERUs. The estimated median mass wasting index is about the 60th percentile; this is corroborated by the stream type group composition. The potential hazard for sediment to be delivered to streams is at about the 50th percentile. Overall, the recovery potential of streams within this ERU is low (20th percentile), due to slow and generally poor recovery potential associated with the characteristic steep A-stream types, and entrenched, unstable F- and G-stream types.

ERU 7: Northern Glaciated Mountains

Three subsection groups dominate this ERU:

- M333-03, characterized by glaciated mountains of granitic and metasedimentary rocks, all of which have been modified by glacial and fluvial processes.
- M333-02, characterized by intermontane basins, valleys, and till plains of lacustrine, outwash, alluvium, and till.
- M333-04, characterized by mountains and breaklands of granitic and metasedimentary rocks.

This area has been modified mainly by fluvial and colluvial processes with some frost churning and alpine glaciation at high elevations. Alluvium occurs in 73 percent of all subwatersheds, with an average composition of 24 percent; open water occurs in 37 percent of all subwatersheds, with an average composition of 5 percent.

High mountains have cold moist soils with volcanic ash, dark topsoils rich in organic matter; high-mountain basin floors have soils with a water table near the surface and organic topsoils. Mid-elevations have cool, cobbly and stony soils with some volcanic ash influence and other soils with dark topsoils rich in organic matter. On valley floors and foothills along major drainages are warm dry soils that include stratified, gravelly soils, and cobbly well-drained soils with dark topsoils on terraces; floodplains have poorly drained soils. On foot slopes above the valley floor are soils formed in till and colluvium. Many of these soils have dark topsoil rich in organic matter.

Flathead Valley Section—These soils are generally cool or cold. Most soils in the mountains have light-colored surface layers. Many of these are young to weakly developed soils with some having subsoil accumulations of clay. Some soils have a thin to thick deposit of volcanic ash at the surface. The basins and valleys have two general groups of soils. One group has thick, dark topsoil, and the second group includes young to weakly developed soils with little horizonation. In general, these soils are moderately deep to deep with loamy to sandy textures, and most have been strongly influenced by volcanic ash.

Northern Rockies Section—These are generally cool to cold soils. Many are young and poorly developed with little horizonation and usually light-colored surface layers. Some have subsoil accumulations of clay. These soils are generally shallow to moderately deep, with loamy to sandy textures containing rock fragments. Some soils at higher elevations have been moderately influenced by volcanic ash deposits.

The western portion of the Northern Glaciated Mountains is dominated by soils with surface layers derived from volcanic ash. These soils are highly productive, especially where moisture and nitrogen are abundant. Some glacial scouring over this area has resulted in shallow to moderately deep, rocky soils that have lower productivity. Deep soils from lake deposits, while productive, are relatively unstable. Soil organic matter is abundant on volcanic ash soils, but low on some of the soils formed in glacial deposits. Volcanic ash soils can be compacted at all moisture levels. Soils derived from residual materials, or with thin layers of volcanic ash, are moderately productive, limited primarily by moisture and nutrients. Many soils of this area are cold and have short growing seasons. Most soils of this area are generally resilient but have high susceptibility to compaction. Natural mass failure and surface erosion hazards are high.

The central portion of the Northern Glaciated Mountains generally has a mix of continental and maritime climates. Areas with a continental climate have colder soils with high temperature extremes which causes them to be less productive. Volcanic ash caps in this area become thinner as distance from Cascade Mountain Volcanic ash sources increases. Areas of thinner ash are usually less productive than those with thicker ash caps. Soils of this area are generally resilient but highly susceptible to compaction. Natural mass failure and surface erosion hazards are high.

The eastern portion of the Northern Glaciated Mountains is dominated by a temperate continental climate and has minor amounts of volcanic ash. This combination contributes to a predominance of soils that are generally shallow to moderately deep, have low productivity and resiliency, and are susceptible to compaction. Both natural mass failure and natural surface erosion hazards are moderate to high.

This ERU is in the second highest class of relative relief (along with ERUs 8, 9, and 12) and second highest class for slope (21%) along with ERU 9. It is in the second highest class for annual precipitation (87 cm), and is in the highest class for summer precipitation (15 cm). Across all ERUs, this ERU has among the lowest maximum winter temperatures.

The major potential vegetation types of this ERU are warm dry (F33), cool moist (F22), and cool dry (F23) forestlands; and each type has constancy values of 56 percent to 76 percent.

The dominant valley bottom settings within this ERU include the following: steep confined valleys (VB 1) having 85 percent constancy across all subsampled watersheds and about 38 percent average composition. Broad, gently sloping valleys (VB 5 and 9) also occur with an 80 percent constancy and 17 percent average composition. Additionally, steeply sloping, moderate to unconfined valley bottoms (VB 2) occur with a 72 percent constancy and 16 percent average composition.

The dominant stream types observed in subsample watersheds are steep, step-pool A-stream types (expected to have cobble and gravel beds and banks); rapids-dominated B-stream types; and meandering, alluvial C-stream types with well-developed floodplains. Narrow, highly sinuous E-stream types also occur with a 50 percent constancy and 5 percent average composition. Entrenched, meandering, unstable F-stream types are also scattered throughout the ERU, having 15 percent constancy across all watersheds and 16 percent average composition, where present. Wetlands and lakes were present in the majority of subsampled watersheds (52% and 70% constancy, respectively).

The erosion potential, given current vegetation, is among the highest across all ERUs (about the 70th percentile). Median mass wasting hazard and potential delivery of sediment to streams is also high, reflecting the characteristic steep slopes and high drainage density present. The overall recovery potential following disturbance is generally good, reflecting the likely stability of the steeper stream types, and the long-term natural recovery potential of the alluvial channels.

ERU 8: Lower Clark Fork

One subsection group dominates this ERU: M333-04, characterized by mountains and breaklands of granitic and metasedimentary rocks, all of which have been modified mainly by fluvial and colluvial processes with some frost churning and alpine glaciation at higher elevations. This ERU has among the highest relative relief of all ERUs (along with ERUs 1, 7, and 13), the highest class of average slope (26%), and the highest class of annual precipitation (111 cm). It has the lowest value for winter solar radiation (0.0023 joules/m^2). The major potential vegetation types present are cool dry (F23), cool moist (F22), and warm dry forestlands (F33). Constancy values for each of these are greater than 70 percent.

Cool to cold mountain soils dominate this area and thick deposits of volcanic ash occur over most of the landscape. Most soils have light-colored surface layers, and a few have dark-colored surface layers. A few soils have subsoil accumulations of clay. These soils are generally shallow to moderately deep with loamy to sandy textures.

The Lower Clark Fork ERU is characterized by thick volcanic ash deposits that were not altered by continental ice sheet flows. Most of this section occurs at low- to mid-elevations where temperature and moisture are favorable to plant growth. The suitable climate, thick volcanic ash, and moderate to highly weathered soils with few restrictive layers contribute to very productive soils in this area. These soils are generally resilient but susceptible to compaction. Natural mass failure and surface erosion hazards are moderate to high.

Steep confined valley bottoms (VB 1) occurred in all subsampled watersheds, with an average composition of 51 percent. Moderately confined and moderate gradient valley bottoms and broad unconfined valleys also occurred in all watersheds, with about 14 percent average composition. Steep A-stream types (having probable cobble and gravel beds and banks) dominate the subsampled watersheds. Alluvial, meandering C-stream types also occurred in all subsampled watersheds, with about 18 percent average composition.

Given current vegetation patterns, upland erosion potential is estimated as moderate, relative to all other ERUs. Mass wasting potential, however, is the highest of all ERUs, reflecting the steep A-channels with gravel and cobble beds and banks. The potential for sediment to reach streams is also very high, relative to all ERUs, with most watersheds in the ERU ranking around the 90th percentile. These watersheds are fairly sensitive to

increased streamflow and sediment, both onsite (about 70th percentile), and downstream due to transfer effects (about 60th percentile). Riparian vegetation is relatively insignificant in maintaining stream channel morphology. Watersheds in this ERU show the highest sensitivity to disturbance of all ERUs.

ERU 9: Upper Clark Fork

Four subsection groups dominate this ERU:

- M332-05, characterized by glaciated mountains and gneiss with lesser amounts of volcanic and sedimentary rocks; all have been modified by glacial, periglacial, fluvial, colluvial, and mass wasting processes.
- M332-07, characterized by mountains of igneous and metamorphic rocks with lesser amounts of sedimentary rocks; all have been modified by fluvial, colluvial mass wasting processes.
- M332-08, characterized by mountains of igneous, sedimentary and metamorphic rocks; all have been modified mainly by fluvial and colluvial processes with lesser amounts of glaciation, frost churning, and mass wasting.
- M332-04, characterized by intermontane basins and valleys of alluvium, lacustrine and loess deposits; all have been modified by fluvial, mass wasting, glacial, and aeolian processes.

Alluvium is found in 86 percent of the subwatersheds with an average composition of 15 percent, where present.

Cool to cold soils are common and usually have little development and light-colored surface layers. There are significant areas of rockland and talus. Some soils in basins have dark-colored surface layers rich in organic matter, and others have light-colored surface layers that are low in organic matter. Soils with dry moisture regimes probably occur. These soils are generally shallow to moderately deep, with loamy or sandy texture containing large amounts of rock fragments. Some soils at higher elevations are moderately influenced by volcanic ash.

In the Upper Clark Fork, soil productivity is generally low; however, some soils have minor amounts of volcanic ash that make them slightly more productive. Soils in the Bitterroot Valley are deep and productive. The most limiting factors for productivity are shallow soils, large amounts of talus and rock outcrops, and low temperatures. Soils are generally less resilient and less susceptible to compaction in this area. Natural mass failure hazard is moderate, and natural surface erosion hazard is moderate to high.

This ERU has the third highest average maximum elevation (2,432 m); only ERUs 12 and 13 have higher elevations. It has the fourth highest average slope (22%), and moderate relative relief. It is approximately equal to ERUs 7, 8, and 9 for highest summer precipitation (15 cm). Along with ERUs 7, 8, and 11, this ERU has the lowest maximum winter temperatures (-0.3° C). The major potential vegetation types of this ERU are warm dry (F33), cool dry (F23), cold wet (F11), and cold moist (F12) forestlands. Percent constancy values for each major type vary from 45 percent to 94 percent.

Steep confined valley bottoms (VB 1) occur in all Upper Clark Fork subsample watersheds, comprising about 50 percent average composition. Moderate gradient, moderately confined valley bottoms (VB 5), and steep moderately confined valley bottoms (VB 2) occur in virtually all subsampled watersheds within this ERU. Where these valley types occur, they comprise 13 percent and 11 percent average composition respectively. Steep, step-pool A-stream types predominate the subsampled watersheds, and rapids-dominated B-stream types were observed with about 15 percent average composition within all subsampled watersheds. Meandering, alluvial C-stream types and narrow and highly sinuous E-stream types were observed in about one-half of the watersheds, comprising 8 percent and 6 percent of the stream types, where present. These low gradient streams likely have beds and banks composed of cobbles,

gravels, and sand. Wetlands and lakes occurred in 61 percent and 67 percent of the subsampled watersheds, respectively.

The upland erosion potential for the Upper Clark Fork ERU is at the 50th percentile, and its mass wasting hazard is at the 60th percentile. The potential for sediment delivery to streams is ranked at the 60th percentile of all ERUs. Although bank erosion potential is locally significant for C-, E-, F-, and G-stream types, overall bank erosion potential is ranked at about the 30th percentile. The inherent recovery potential of these watersheds is quite high (70th percentile).

ERU 10: Owyhee Uplands

Three subsection groups dominate this ERU:

- 342-02, characterized by plateaus and high plains of basalts and tuffs; all have been modified by fluvial and aeolian processes.
- 342-06, characterized by mountains composed mainly of tuffs and basalts; all have been modified by fluvial and aeolian processes.
- 342-03, characterized by plateaus and high plains of fluvial and lacustrine sediments and ash deposits that have been created by aeolian, fluvial, and lacustrine processes.

Alluvium is present in 68 percent of the subwatersheds with average composition of about 21 percent.

This area contains dry soils with light-colored surface layers, young soils with little or weakly developed horizonation, and soils with thick, dark-colored surface layers. The soil horizons may be the result of movement and accumulation of salts, carbonates, or silicate clays, or of cementation by carbonates or silica. Most soils are warm to cool and dry to moist. Cold soils occur at high elevations.

In the Owyhee Uplands, moisture is the principal limiting factor to plant growth. The most productive portions of this area are the riparian and wetland settings, which are much more productive than the most productive upland sites. On upland sites, higher elevation areas are usually the most productive. Soils that occur on lower elevations are often shallow to bedrock, or have hardpans that result in low productivity. Soils of this area are generally resilient but susceptible to compaction. Natural mass failure and natural surface erosion hazards are low.

The Owyhee Uplands ERU has relatively high elevation subwatersheds (average elevation is about 1,400 m) and is among the three lowest ERUs in terms of relative relief and average slope (9%), with numerous outliers that indicate the presence of localized steep slopes. Along with ERUs 4 and 5, this ERU has the lowest annual precipitation (30 cm) and has some of the lowest summer precipitation values (4 cm). It has the highest August temperature (18° C), the third highest winter temperature (-1.4° C), and is in the highest class for winter solar radiation. The major potential vegetation types present are warm dry (S33), warm very dry (S34), cool moist (S22), and cool dry (S23) shrublands. Constancy values for each of these major types vary from 35 percent to 77 percent.

Gentle slopes in moderately confined valley bottoms (VB 8) occur in all watersheds, with an average composition of 25 percent. Moderate slopes in confined to moderately confined valley bottoms were also present (VBs 4 and 5 are codominant, occurring in 96% of the subsampled watersheds and comprising about 20% average composition). Steep confined valleys occur in most watersheds, but comprise only about 15 percent of the total valley bottom settings.

Steep, step-pool, A-stream types and rapids-dominated B-stream types occur in all subsampled watersheds, but comprise only about a one-quarter of the observed stream types. Meandering, alluvial C-stream types with well-developed floodplains were observed in most watersheds (92%) and represented about 20 percent of the stream type pattern composition. Braided channels (88% constancy across watersheds with 9% average composition) and entrenched, G-stream types, as well as entrenched, meandering F-stream types

(76% constancy with 52% average composition) also occur in the subsample watersheds.

Upland erosion potential, given current vegetation, ranks at about the 60th percentile over all ERUs. Mass wasting potential is quite low, second to the Great Basin (ERU 4). Sediment delivery hazard is similarly low (about the 20th percentile), reflecting the moderate slopes, low stream dissection, and sparse rainfall. Potential bank erosion is quite high (median value 70th percentile), with vegetation moderately important in maintaining width to depth ratios. Inherent recovery potential following disturbance is among the lowest of all ERUs, reflecting the high probable occurrence of unstable, entrenched channels (that is, G- and F-stream types).

ERU 11: Upper Snake

Two subsection groups dominate this ERU:

- 342-02, characterized by plateaus and high plains of basalts and tuffs that have been modified by fluvial and aeolian processes.
- 342-06, characterized by mountains composed mainly of tuffs and basalts that have been modified by fluvial and aeolian processes.

Alluvium occurs in 84 percent of the subwatersheds, with an average composition, where present, of 37 percent.

Northwestern Basin and Range Section—The soils that occur in the drier areas have light-colored surface layers with subsoil accumulations of clay or hardpans. Large areas have saline-sodic soils.

Snake River Basalts Section—There are two major groups of soils. One group is dry with light-colored surface layers, and some have accumulations of clay in the subsoil or have hard pans. The second group occur in more moist areas and have thick dark topsoils.

This ERU is characterized by high elevations (average of approx. 1,700 m), low relief, and low average slope (10%). It is among the lowest class of annual precipitation (31 cm), and summer precipitation (6 cm), and has high winter solar radiation (0.0045 joule/m^2). This ERU has the third highest average daily August temperature (behind only ERUs 5 and 10).

Moisture is the principal limiting factor for vegetation growth in the Upper Snake ERU. Riparian areas and higher elevation sites are wetter, have the most organic matter, and are generally the most productive sites. Low elevation sites with the least precipitation and areas with saline-sodic soils are the least productive environments. Soils of this area vary in their resilience and susceptibility to compaction. Natural mass failure hazard is low and natural surface erosion hazard is moderate.

The major potential vegetation types present are warm dry (S33) and warm moist shrublands (S32); hot very dry forestlands (F44); and cool moist shrublands (S22). These types generally coincide with the eastern portion of the Northwestern Basin and Range Section (342B), and the Snake River Basalts Section (342D).

Moderately confined valley bottoms on gentle slopes predominate this ERU, comprising 29 percent of the total valley bottom composition and occurring in all subsampled watersheds. Moderately confined valley bottoms on moderate slopes are co-dominant (with 80% constancy and 20% average composition, where present). Moderate gradient, rapids-dominated B stream types occur in 93 percent of subsampled watersheds, and comprise 28 percent of the average stream type pattern composition. Steep, step-pool A stream types occur in almost 80 percent of the subsampled watersheds, with an average composition of almost 40 percent. Entrenched, gully-like G stream types also occur as a minor component (4% average composition) within a majority of watersheds in the Upper Snake (71%). Channelized and trenched streams are also common, occurring in 57 percent of subsampled watersheds and representing 7 percent average composition.

Upland erosion potential, given current vegetation patterns, ranks at about the 60th percentile, but mass wasting and potential sediment delivery to streams is low relative to other ERUs. The overall onsite sensitivity of these watersheds to increased

flow and sediment ranks at about the 50th percentile, but there is a large spread in the distribution of index values. The Upper Snake ERU is distinguished by relatively high streambank erosion potential (about the 65th percentile). Riparian vegetation is especially important for maintaining channel morphology (90th percentile) in these settings. The inherent stream channel recovery potential is quite low (about the 40th percentile).

ERU 12: Snake Headwaters

Four subsection groups dominate this ERU:

- M331-06, characterized by mountains of sedimentary and volcanic rocks; all have been modified by colluvial, fluvial, residual, glacial, and periglacial processes.
- M331-02, characterized by intermontane basins and valleys of valley fill, alluvium, and lacustrine materials overlying volcanic and sedimentary rocks.
- M331-03, characterized by glaciated mountains of volcanic and sedimentary rocks; all have been modified by colluvial, fluvial, residual glacial, and periglacial processes.
- M331-04, characterized by glaciated mountains of volcanic and sedimentary rocks; all have been modified by colluvial, fluvial, residual, and glacial processes.

Alluvium is present in 88 percent of the subwatersheds, with average composition, where present, of 19 percent.

Most soils are young to weakly developed and have very poor horizonation; others have subsoil accumulations of clay, thick dark-colored topsoils, or are organic soils. Soil temperatures range from cool to cold, and soil moisture ranges from dry to wet.

The Snake River Headwaters include some of the highest elevations in the Basin. Soil productivity is generally moderate and many soils are cold, shallow to moderately deep, rocky, or stony. Alpine areas consist mostly of rock outcrops and talus. Glaciation has produced many areas of shallow soils and rock outcrop. Soil moisture can be limiting in some areas, and most soils are moderately resilient and have low to moderate susceptibility to compaction. Natural mass failure hazard is moderate to high due to the interbedded sedimentary rocks that weather to form slip surfaces. Natural surface erosion hazard is moderate to high.

This ERU has the highest average elevations of all ERUs (approx. 2,200 m) with relative relief and averages slope (18%) in the mid-range for all ERUs. It has high winter solar radiation (0.0048 joule/m^2), a moderate level of summer precipitation, and low maximum winter temperatures. The major potential vegetation types present are cool moist shrublands (S22), cool dry forestlands (F23), warm dry forestlands (F33), and warm dry shrublands (S33). Constancy values for these types vary from 45 percent to 67 percent.

Steep, moderately confined valleys (VB form 2) dominate this ERU, followed by moderately confined valleys on moderate slopes (VB 5; 100% constancy and 17% average composition). Broad, gently sloping valleys (VB 9; 100% constancy and 15% average composition) are also present. Steep, step-pool, A-stream types occur in all subsampled watersheds. Meandering, alluvial channels with well-developed floodplains also occur in all subsampled watersheds, and represent about 18 percent of stream type composition where present. Narrow, highly sinuous, low gradient E-stream types occur in almost half of all subsampled watersheds, but are more limited in extent (that is, represent 4% average composition, where present). Braided channels also occur over small areas in a majority of watersheds (about 60%). Lakes occur in 76 percent of the subsampled watersheds, representing about 6 percent of the aquatic pattern composition.

The mass wasting index is high (the 80th percentile) for the Snake Headwaters ERU; however, the potential for sediment delivery to streams is only moderate due to low drainage densities. Maintenance of riparian vegetation is fairly important, relative to other ERUs, reflecting the occurrence of C- and E-type channels, and gully-like G-stream types.

ERU 13: Central Idaho Mountains

Three subsection groups dominate this ERU:

- M332-07, characterized by mountains of igneous and metamorphic rocks with lesser amounts of sedimentary rocks; all have been modified by fluvial, colluvial, and mass wasting processes.
- M332-05, characterized by glaciated mountains and gneiss with lesser amounts of volcanic and sedimentary rocks; all have been modified by glacial, periglacial, fluvial, colluvial, and mass wasting processes.
- M332-01, characterized by breaklands and foothills of granitic rocks; all have been modified by fluvial, colluvial, and mass wasting processes.

The Central Idaho Mountains ERU generally coincides with the Idaho Batholith Section (M332A), the Challis Volcanics Section (M332F), and a part of the Beaverhead Mountains Section (M332E).

Idaho Batholith Section—These are mostly cool and cold soils of the mountains. Most are immature soils with few diagnostic horizons, but a few have clay-enriched subsoils. Most soils have light-colored surface layers; and some have thick, dark-colored topsoil. Some areas have soils with thick volcanic-ash surface layers. Soils are generally shallow to moderately deep, with loamy to sandy textures.

Challis Volcanics Section—Two main groups of soils occur in this section. One group has young to weakly developed soils with light-colored surface layers. The second group has more profile development and includes soils with thick dark-colored topsoils and those with clay-enriched subsoils. Most soils have cool to cold temperature regimes, and dry to wet moisture regimes.

Beaverhead Mountains Section—Soils temperatures range from cool to cold. Some soils have light-colored surface layers and possible accumulations of clay in the subsoil. Other soils have thick, dark-colored topsoil. Young, poorly developed soils occur in alluvial valleys. Mountain soils are generally shallow to moderately deep and have loamy to sandy textures with rock fragments. Valley soils are moderately deep to deep and have loamy to clayey textures.

In the northern and western portion of the Central Idaho Mountains ERU, soil productivity is generally moderate; however, some areas have shallow soils with coarse textures and low organic matter, which makes them less productive. Deep soils and volcanic ash accumulations occur in this area, however, and are commonly very productive, moderately resilient, and moderately susceptible to compaction. Natural mass failure hazard is high, and natural surface erosion hazard is moderate.

In the southcentral part of this ERU, soil productivity is generally moderate to low. This area includes some of the highest elevations in the Basin; most soils are cold, shallow to moderately deep, rocky, and stony. The alpine areas that occur consist mostly of rock outcrop and talus. Glaciation has also produced many areas of shallow soils and rock outcrop. The soils of this area are often moisture-limited, have low to moderate resiliency, and are moderately to highly susceptible to compaction. Natural mass failure hazard is moderate to high, with mass failures and rock falls common at higher elevations. Natural surface erosion hazard is moderate to high.

In the eastern portion of the Central Idaho Mountains ERU, soil productivity is generally low; however, some valley areas with deeper soils have moderate to high productivity. Soils of this area generally have low resiliency and are moderately susceptible to compaction. The natural mass failure hazard is low, and the natural surface erosion hazard is moderate to high.

The Central Idaho Mountains ERU is within the second highest elevation class (average elevation is approx. 1,900 m). It has the highest relative relief and highest class of average slopes (26%) of all ERUs. This ERU also has high winter solar radia-

tion values. The major potential vegetation types present are warm dry (F33), cool dry (F23), cold dry (F13) forestlands; and cool moist shrublands (S22).

Steep confined valleys (VB 1) dominate this ERU. Moderately confined valleys with moderate slopes (VB 5) and steep slopes (VB 2) are also common. Steep step-pools and cascade streams (Stream type-A) occur in all subsampled watersheds and comprise a high average composition when present (66%). On more moderate slopes, rapids dominated B-stream types, and localized occurrences of braided D-stream types are common (93% and 45% constancy respectively). Highly sinuous, narrow, riffle-pool streams (E-types) occur in 45 percent of all subsampled watersheds, comprising 7 percent of the average stream composition where they are present. Unstable, entrenched F-types, probably with cobble, gravel, or sand bed and banks, occur in one-third of all watersheds, with 5 percent average composition, where present.

Upland erosion potential, given current vegetation, is about average relative to all ERUs. Mass wasting potential and potential delivery of sediment to streams is quite high (both are at the 65th percentile). The overall sensitivity of these watersheds to increased sediment and streamflow is fairly low (25th percentile). There are, however, numerous watersheds containing the unstable entrenched F-stream types and gully-like G-stream types. The overall rating for potential downstream transfer effects of disturbances caused by increased streamflow and sediment is moderately high (about the 60th percentile), again reflecting unstable channels that can introduce large amounts of channel-derived sediment into the drainage network.

Hydrologic Integrity Assessment

Estimation of hydrologic integrity across the Basin was complicated by a lack of consistent finer scale data. Stream parameters such as bankfull width, depth, and gradient and streambed substrate composition were generally lacking for most watersheds. These parameters are required if site-specific quantifications of hydrologic integrity are to be made in the Basin and need to be incorporated into future integrated aquatic inventories.

Because of the lack of finer-scale stream morphometric data, a more generalized probabilistic approach was used in determining subbasin hydrologic integrity. Information concerning the resiliency of watersheds to disturbance and estimates of past management activity disturbance to watersheds were both used in determining the hydrologic integrity of subbasins. Rangeland and forested watersheds were assessed independently in this analysis to facilitate characterization of these environments separately at the subbasin level. Subwatersheds (6th-field HUCs) were assigned to a forested type if 20 percent or more of a subwatershed was comprised of forested potential vegetation environments as described earlier in this chapter on Regional Potential Vegetation Classification. Subwatersheds with at least 20 percent or more of rangeland potential vegetation were assigned to a rangeland environment type. The following is a brief description of the methods used in determining the hydrologic disturbance, resiliency, and hydrologic integrity of forest and rangeland environments by subbasin (4th-field HUCs) in this analysis.

Assessment of Hydrologic Disturbance

Impact variables that were considered to be potentially detrimental to the hydrologic integrity of a watershed and that were available continuously across all the watersheds of the Basin were identified in this analysis. These variables included: surficial mining, dams, cropland conversion, and roads.

To facilitate scaled comparisons of these impact variables across the Basin, each subwatershed was assigned to an impacted or non-impacted class for each of the four impact variables studied based on the presence of the impact variable. The percent of impacted subwatersheds within each subbasin was then calculated by impact variable type to produce a coarser-scale description of probable subbasins with impaired hydrologic function (that is, hydrologic disturbance). The four impact variable type

percent values for each subbasin (that is, mining, dams, cropland, and roads) were then converted to cumulative frequency distributions that facilitated general comparisons of relative impact differences across all 4th-field HUC subbasins (that is, each subbasin was assigned a number between 0 and 100 that reflected the percent of other subbasins having an equal or lower value for each of the four impact variables studied).

A generalized description of hydrologic disturbance was constructed for the Basin by summing all four impact variable values for each subbasin by forest and rangeland environment stratifications. This resulted in a potential score for each subbasin ranging from 0 (least impacted) to 400 (most impacted). This summary impact value for each 4th-field HUC subbasin was then converted to a cumulative frequency value that reflected overall relative hydrologic impact differences across all forest and rangeland subbasins. These cumulative frequency values were converted into three hydrologic disturbance class ratings as follows:

- Subbasins with values of 0 to 33 percent were assigned to a low hydrologic disturbance class (that is, they had the lowest overall percent impact by the four variables studied).
- Subbasins with values of 34 to 66 percent were assigned to a moderate hydrologic disturbance class.
- Subbasins with values greater than 66 percent were assigned to a high hydrologic disturbance class.

Maps were produced from these disturbance class ratings to illustrate relative hydrologic disturbance class differences between forested (map 2.34) and rangeland (map 2.35) environments by subbasin.

An assessment of probable riparian area disturbance on rangeland portions of each subbasin was also performed in this analysis. Because detailed information concerning actual riparian conditions was not available for many of the subbasins, riparian disturbance was estimated based on information concerning the sensitivity of streambanks to grazing and the sensitivity of stream channel function to the maintenance of riparian vegetation. In this approach, the resiliency of riparian areas to grazing was used to infer probable riparian area disturbance given the fact that many riparian areas in the Basin have experienced historically high grazing pressure which may still persist today. Accordingly, areas with low relative grazing resiliency were considered to potentially have high riparian disturbance while areas with relatively high grazing resiliency were considered to potentially have lower riparian disturbance. Cumulative frequency distributions were calculated for the combined streambank sensitivity and riparian vegetation sensitivity scores of each rangeland subwatershed which were then averaged by subbasin.

Stratification of these cumulative frequency values into low (0 to 33%), moderate (34 to 66%), and high (greater than 66%) disturbance classes facilitated construction of a map that displays probable relative riparian area disturbance class differences of rangelands by subbasin (map 2.36).

Assessment of Hydrologic Resiliency

The hydrologic and riparian disturbance ratings discussed above reflect relative management impact differences across subbasins. These ratings do not, however, indicate the resiliency of such watersheds to disturbance (that is, their ability to recover following impact). To better understand the potential hydrologic integrity of the watersheds and subbasins within the Basin, a variety of resiliency ratings were developed for each subwatershed and subbasin. These ratings were used in conjunction with the hydrologic impact ratings discussed above in the assessment of overall hydrologic integrity. For example, areas with high hydrologic impact and high stream and riparian vegetation sensitivity are considered to have the lowest probable hydrologic integrity across the Basin. Areas with high hydrologic impact and low stream and riparian vegetation sensitivity, however, would likely possess higher hydrologic integrity because they are better able to absorb such impacts without loss of hydrologic function.

Map 2.34—Relative hydrologic disturbance ratings of forest environments within subbasins.

Map 2.35—Relative hydrologic disturbance ratings of rangeland environments within subbasins.

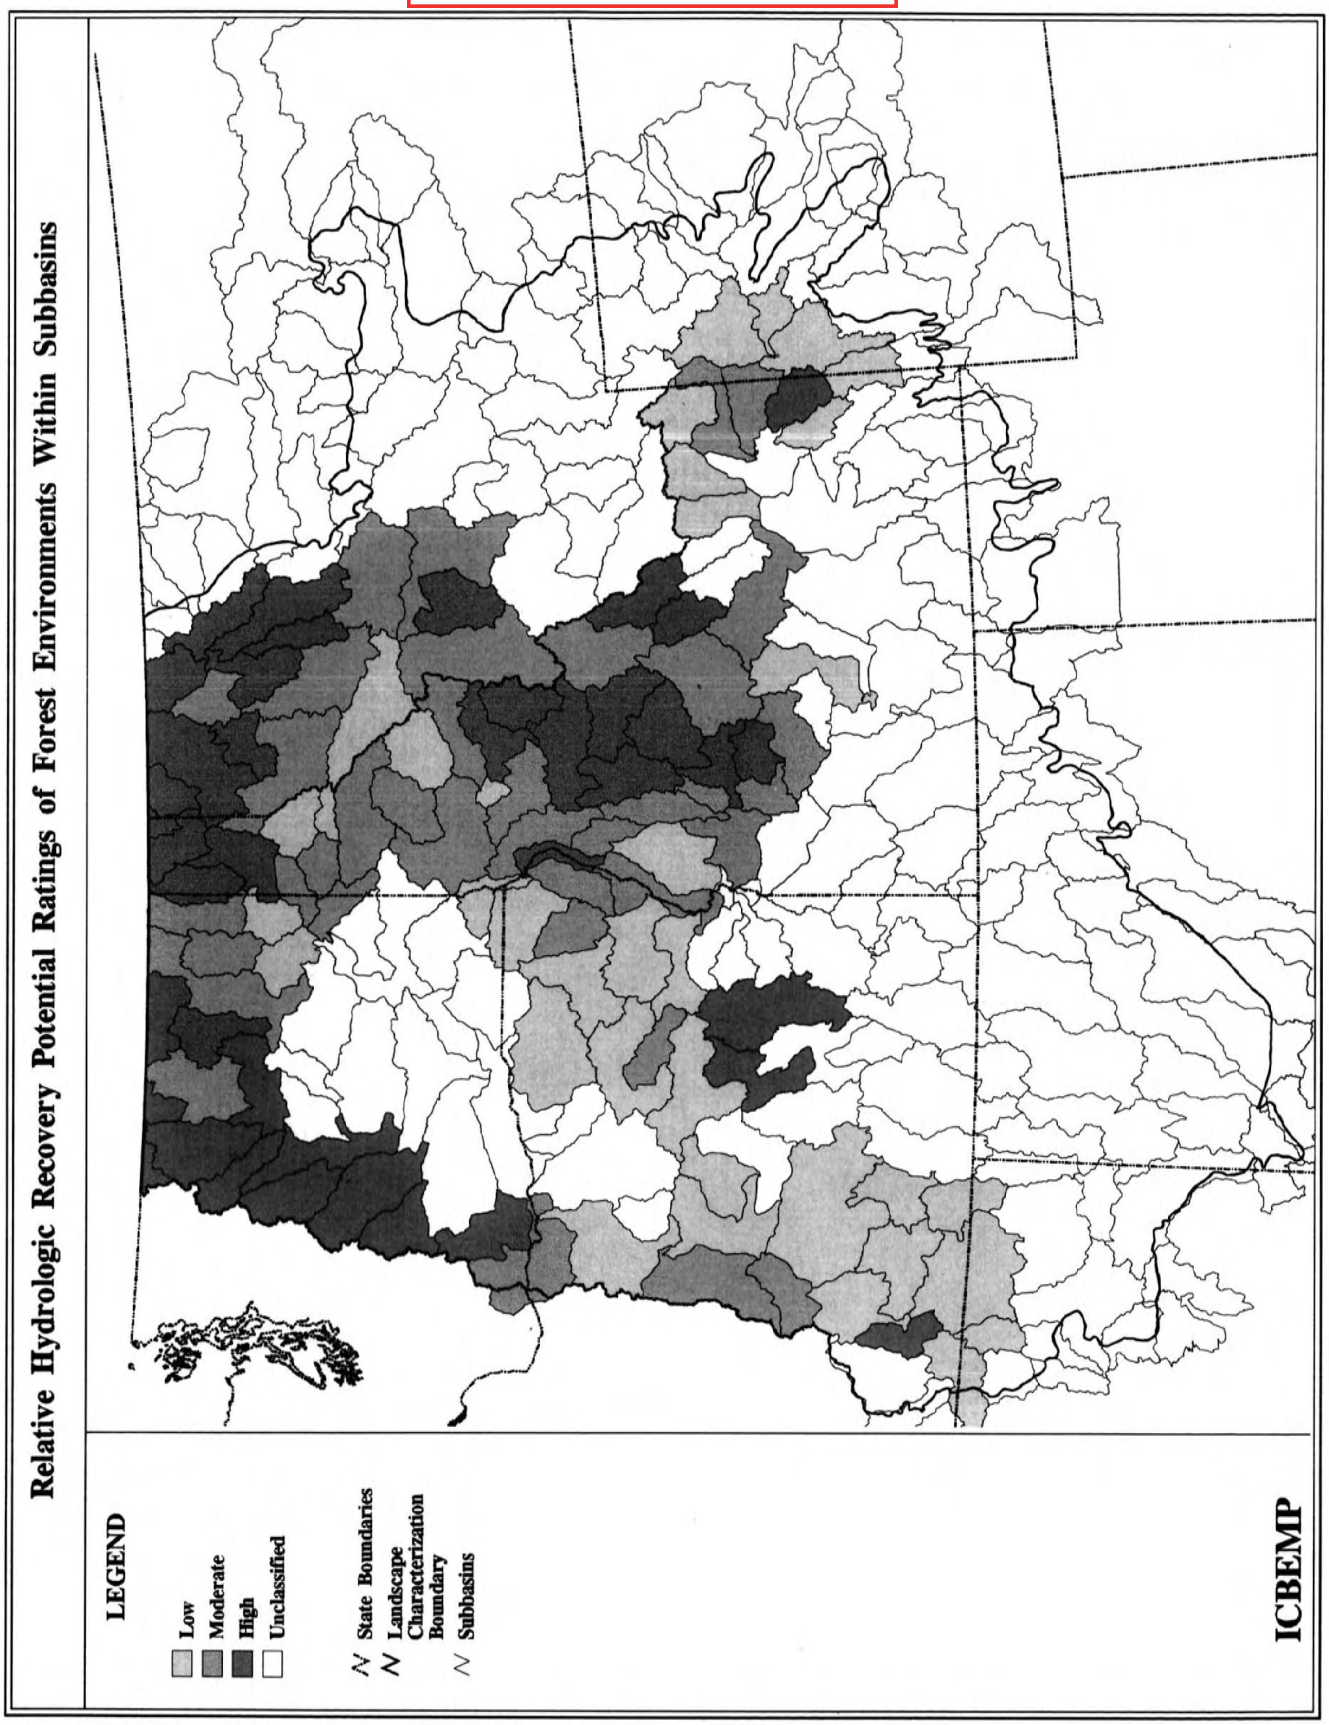
Map 2.36—Relative riparian disturbance ratings of rangeland environments within subbasins.

For these reasons, hydrologic resiliency ratings should always be considered when interpreting the impacts of past management activities on hydrologic system integrity.

The following is a brief description of the hydrologic resiliency ratings considered in this analysis:

- Road Sediment Hazard: This hazard rating provides a relative description of areas where roads are likely to contribute sediment to streams following construction. Variables considered in this rating include road erosion rates as interpreted by lithologic groups and sediment delivery potential, which considers the average slope and dissection of a watershed. This variable is used in assessing potential impacts to streams following road construction.
- Hillslope Sediment Hazard: This hazard rating provides a relative description of the sediment likely to reach a stream under conditions of no vegetation or ground cover (that is, following wildfire or heavy vegetation extraction). Variables considered in this rating included bare soil erosion rates and sediment delivery potential.
- Stream Sensitivity: This sensitivity rating provides a relative description of watersheds where increased sediment or streamflow are likely to adversely affect stream hydrologic function. This rating is derived from an estimate of the probable stream types within a watershed and their sensitivity to increased sediment and flow.
- Bank Sensitivity: This sensitivity rating provides a relative description of watersheds where streambanks are likely to be adversely affected by management activities (that is, areas where streambanks are sensitive to disturbance). This rating is derived from an estimate of the probable stream types within a watershed and their inherent streambank sensitivity.
- Vegetation Sensitivity: This sensitivity rating provides a relative description of watersheds where riparian vegetation is important to the maintenance of stream function. This rating is derived from an estimate of probable stream types within a watershed and their sensitivity to altered riparian vegetation.
- Hydrologic Recovery Potential: This potential rating provides a relative description of the potential that a watershed has for recovery of hydrologic function following disturbance. This rating is derived from an estimate of probable stream types within a watershed and their potential for recovery following disturbance. This variable is displayed for forestlands on map 2.37 and for rangelands on map 2.38.

The above hydrologic resiliency ratings were calculated individually for each subwatershed and subbasin. Cumulative frequency values for these variables were also calculated for each 4th-field HUC subbasin by forest and rangeland environments. Summary statistics for these resiliency variables were calculated for six forested environment clusters (table 2.23) and six rangeland environment clusters (table 2.24) that are described later in this chapter. Methods used in the identification of the Forest and Rangeland Environment clusters are described in the Integrated Assessment (Quigley and others 1996).



Assessment of Hydrologic and Riparian Integrity

Generalized assessments of hydrologic integrity were made for the forest and rangeland subwatersheds of each subbasin by combining average cumulative frequency values for hydrologic disturbance and hydrologic recovery potential. In this analysis, hydrologic disturbance values were subtracted from 100 to make them compatible with hydrologic recovery potential ratings in the calculation of hydrologic integrity.

(Note: x = Mean; SD = Standard Deviation)

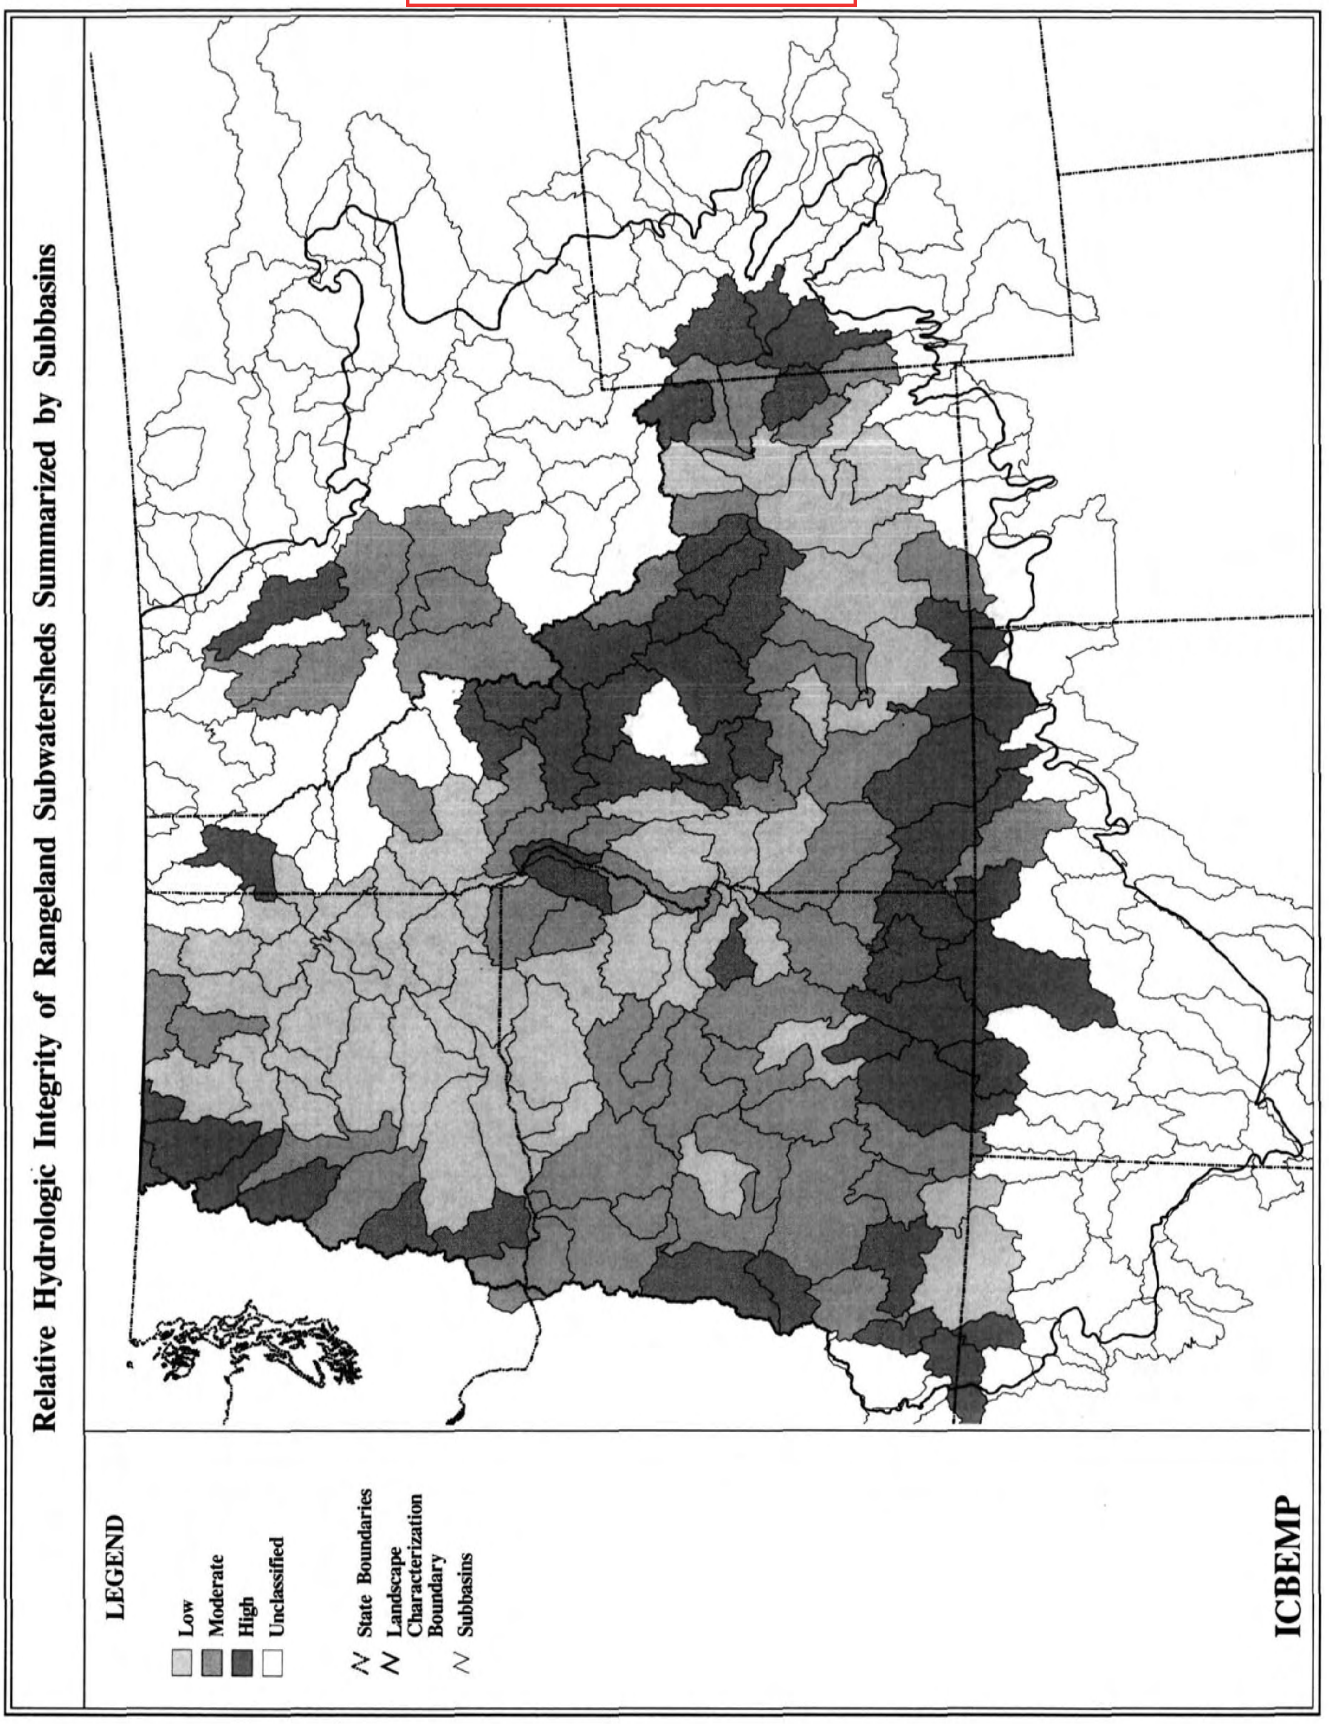
The combined values of the adjusted hydrologic disturbance and hydrologic recovery potential ratings for both the forest and rangeland environment settings of each subbasin were used to produce new cumulative frequency distributions of hydrologic integrity by subbasin. These scores were used to produce maps of relative hydrologic integrity differences across both forested (map 2.39) and rangeland (map 2.40) environments. Class ratings used in construction of these maps include low (0 to 33%), moderate (34 to 66%), and high (greater than 66%) classes (that is, the percent of other 4th-field HUC subbasins with equal or smaller hydrologic integrity values). Hydrologic integrity ratings were also developed in a similar manner for the forest and rangeland subbasins identified in the *Integrated Assessment* (Quigley and others 1996). These ratings, however, were based on relative differences among the 112 forest and 86 rangeland subbasins identified which resulted in different subbasin scores than those presented in maps 2.39 and 2.40 (that is, the areas used in calculating relative subbasin values were different).

The relative integrity of rangeland riparian areas was calculated in a similar manner to that used in defining general hydrologic integrity. The average relative riparian disturbance and hydrologic recovery potential ratings for each subbasin were combined in determining the probable riparian integrity value of each subbasin. Cumulative frequency distributions of these values were used to produce a map of relative riparian area integrity across the different rangeland environments of the Basin (map 2.41).

The integrity values described above assume that areas with high impact (disturbance) and low recovery potential (resiliency) will often have higher probabilities of altered hydrologic functions than other areas; consequently, in this chapter, these areas are described as possessing low integrity. Conversely, areas with low relative impact by mining, dams, roads, cropland conversion, and grazing with high recovery potentials are considered to have the highest probable hydrologic and riparian integrity. The integrity values presented in this chapter reflect probabilities of finding altered hydrologic functions within 4th-field HUC subbasins based on relative differences between subbasins. Validation of these ratings was not feasible (due primarily to the lack of appropriate finer-grain data within the Basin). Accordingly, the hydrologic integrity, disturbance, and resiliency values presented should only be used for general planning purposes and should not be used in prescriptive project design. Information presented in this section is appropriate to the description of relative differences across the Basin at the 4th-field HUC subbasin level. Application of this information to more detailed planning at the subregional or landscape levels of assessment may be inappropriate.

Forest Cluster Hydrologic Integrity Narrative Descriptions—The following is a brief description of the hydrologic integrity of the six forest clusters (map 2.42) addressed in the *Integrated Assessment.*

Forest cluster 1: Hydrologic integrity of these subbasins is the highest of any forestlands. Disturbance of hydrologic function due to past management activities is low, and the potential for streams to recover following disturbance is generally moderate to high. Steep slopes, high drainage densities, and erosive soils are commonly found on the forested lands of these subbasins. These factors contribute to high sediment hazard potential ratings for these subbasins following roading or large crown-consuming fires. Accordingly, these subbasins are considered to be sensitive to the construction of new roads, and fuel management plans should be developed to limit the risk of extensive wildfires in protecting the hydrologic integrity of these subbasins. Stream channels of these environments generally display a moderate sensitivity to increased sediment and flow.



Forest cluster 2: Hydrologic integrity of the forestlands within these subbasins is relatively high. Disturbance of hydrologic function due to past management activities is generally low, and the potential for streams to recover following disturbance is commonly high. Sediment hazard potentials of these subbasins are similar to Forest Cluster 1, which is high for road construction and wildfires. Stream channels of these environments generally display a low sensitivity to increased sediment and flow.

Map 2.40—Relative hydrologic integrity ratings of rangeland environments within subbasins.

Map 2.41—Relative riparian integrity ratings of rangeland environments within subbasins.

Map 2.42—Forest clusters.

Forest cluster 3: Hydrologic integrity of these subbasins is low to moderate. Disturbance of hydrologic function from past management activities is moderate to high due in large part to roads, mines, and cropland conversion of lower elevation valleys. The potential for streams of these environments to recover following disturbance is moderate. Sediment hazards associated with roads and large crown-consuming fires are moderate and the sensitivity of streams to increased sediment and flow is commonly low to moderate. These subbasins present moderate limitations to management given their hydrologic resiliency; however, past management activities may have already contributed to degraded conditions in some subbasins.

Forest cluster 4: Hydrologic integrity of these subbasins is moderate. Disturbance of hydrologic function from past management activities is moderate due primarily to roads and dams. The potential for streams to recover following disturbance is also moderate. Sediment hazards associated with road construction and stand-consuming fires are moderate. Sensitivity of streams to increased sediment and flow is moderate. These forest environments present good opportunities for hydrologic integrity restoration projects.

Forest cluster 5: Hydrologic integrity of these subbasins is low to moderate. Disturbance of hydrologic function from past management activities is moderate to high, due primarily to dams and to a lesser extent roads and cropland conversion of lower elevation valleys. The potential for streams to recover following disturbance is generally low, which suggests that adverse impacts of previous activities on hydrologic function are still apparent in many subbasins of these forest areas. Due to the gentler slopes, lower dissection, and less erosive soils of these environments, sediment hazards associated with roads and large crown-consuming fires are generally low. Sensitivity of streams to increased sediment and flow, however, is high.

Forest cluster 6: Hydrologic integrity of these subbasins is the lowest of any forestlands in the Basin. Disturbance of hydrologic function from management activities is high due primarily to roads, dams, and cropland conversion of lower elevation valleys. The potential for streams to recover following disturbance is low to moderate, which suggests that adverse impacts of previous management activities on hydrologic function are still apparent in many subbasins of this forest type. Sediment hazards associated with roads are moderate to high; however, those associated with large crown fires are generally low to moderate. Sensitivity of streams to increased sediment and flow in these subbasins is generally low.

Range Cluster Hydrologic Integrity Narrative Descriptions—The following text is a brief description of the hydrologic integrity of the six rangeland clusters (map 2.43) addressed in the *Integrated Assessment* (Quigley and others 1996).

Range cluster 1: The general hydrologic integrity of these subbasins is low to moderate, and riparian environment integrity is commonly low. Disturbance of hydrologic function from past management activities is moderate, due primarily to dams and to a lesser degree roads and cropland conversion of valley bottoms. Grazing impacts to riparian areas are assumed to be moderate to high in many areas. The potential for streams to recover following disturbance is generally low to moderate within these subbasins. Sediment hazards associated with roads and wildfires are moderate to high, and the sensitivity of stream channels to increased sediment and flow is high. Sensitivity of streambanks to disturbance is high and the dependency of stream channel function to the maintenance of riparian vegetation is moderate to high. For these reasons, grazing in riparian areas can have significant impacts on the hydrologic integrity of these subbasins.

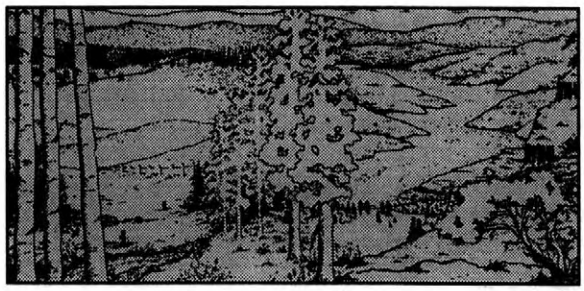
Range cluster 2: The general hydrologic integrity of these subbasins is high and the integrity of riparian environments is also high. Disturbance of hydrologic function from past management activities is low, and grazing impacts to riparian areas

Map 2.43—Range clusters.

are assumed to be generally low. The potential for streams to recover following disturbance is high within these subbasins. Sediment hazards associated with roads and wildfires tend to be some of the highest found on rangelands of the Basin; however, the sensitivity of streams to increased flow and sediment are commonly low to moderate. Sensitivity of streambanks to disturbance is low and the dependency of stream channel function to the maintenance of riparian vegetation is low to moderate. For these reasons, these subbasins support some of the most resilient riparian environments to livestock grazing.

Range cluster 3: The general hydrologic integrity of these subbasins is moderate, and the integrity of their riparian environments is moderate to high. Disturbance of hydrologic function from past management activities is moderate, due primarily to roads and mines and to a lesser degree dams and cropland conversion of valley bottoms. Grazing impacts to riparian areas are assumed to be moderate in most areas. The potential for streams to recover following disturbance is moderate within these subbasins. Sediment hazards associated with roads are high and those associated with wildfires are moderate to high. Sensitivity of streams to increased sediment and flow are generally moderate. Sensitivity of streambanks to disturbance is moderate as is the dependency of stream channel function to the maintenance of riparian vegetation.

Range cluster 4: The general hydrologic integrity of these subbasins is low as is the integrity of the riparian environments they contain. Disturbance of hydrologic function from past management activities is high, due primarily to cropland conversion of valley bottoms and to a lesser degree roads. Grazing impacts to riparian areas are assumed to be moderate where such practices exist. The potential for streams to recover following disturbance is the lowest of any rangeland setting within the Basin. Sediment hazards associated with roads are moderate, and those associated with wildfires are commonly low to moderate. Sensitivity of stream channels to increased sediment and flow is moderate to high, which suggests that the hydrologic integrity of many stream channels may still be impaired due to previous management activities within these subbasins. Sensitivity of streambanks to disturbance is high, and the dependency of stream channel function to the maintenance of riparian vegetation is moderate.



Range cluster 5: The general hydrologic integrity of these subbasins is high, and the integrity of the riparian environments they contain is commonly moderate to high. Disturbance of hydrologic function from past management activities is low, and the assumed impacts to riparian areas by grazing are low to moderate. The potential for streams to recover following disturbance tends to be high within these subbasins. Sediment hazards associated with roads are commonly low to moderate, and those associated with wildfires are moderate. Sensitivity of streams to increased sediment and flow is low to moderate. Streambank sensitivity to disturbance and the dependency of stream channel function to the maintenance of riparian vegetation are low. These subbasins commonly provide the fewest limitations to rangeland management from a hydrologic integrity perspective (that is, they are resilient and have not been heavily impacted in the past).

Range cluster 6: The general hydrologic integrity of these subbasins is low to moderate, and the integrity of their riparian environments is commonly low. Disturbance of hydrologic function from past management activities is moderate to high due to roads, dams, mines, and cropland conversion of valley bottoms. Grazing impacts to riparian areas are assumed to be moderate to high. The potential for streams to recover following disturbance is commonly low to moderate. For these reasons, past disturbances to hydrologic integrity are considered to persist in many of the subbasins within this rangeland theme. Sediment hazards associated with roads and wildfire are moderate, and stream sensitivity to increased sediment and flow is commonly moderate. Sensitivity of streambanks to disturbance and the dependency of stream channel function to the maintenance of riparian vegetation is moderate to high.

Cam Johnston, USDA Forest Service, Northern Region, Fire Sciences Laboratory, Missoula, Montana

Andy Wilson, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Emma Braunberger, USDA Forest Service, Northern Region, Missoula, Montana

John Lane, USDA Forest Service, Northern Region, Missoula, Montana

Gary Raines, U.S. Geological Survey, Reno, Nevada

Bruce Johnson, U.S. Geological Survey

Mapping of Northern Region:

Wayne Barndt, USDA Forest Service, Northern Region, Lolo National Forest, Missoula, Montana

Jerry Niehoff, USDA Forest Service, Northern Region, Idaho Panhandle National Forest, Coeur d'Alene, Idaho

Dale Wilson, USDA Forest Service, Northern Region, Clearwater National Forest, Orofino, Idaho

Pat Green, USDA Forest Service, Northern Region, Nez Perce National Forest, Grangeville, Idaho

Lou Kuennen, USDA Forest Service, Northern Region, Kootenai National Forest, Libby Montana

Dean Siruck, USDA Forest Service, Northern Region, Flathead National Forest, Kalispell, Montana

Bill Basko, USDA Forest Service, Northern Region, Flathead National Forest, Kalispell, Montana

Ken McBride, USDA Forest Service, Northern Region, Bitterroot National Forest, Hamilton, Montana

Bob Spokas, Natural Resources Conservation Service, Montana

Bob Spokas, Natural Resources Conservation Service, Montana

Dave Rupert, USDA Forest Service, Northern Region, Deerlodge National Forest, Butte, Montana

Larry Laing, USDA Forest Service, Northern Region, Helena National Forest, Helena, Montana

Shelly Douthett, USDA Forest Service, Northern Region, Helena National Forest, Helena, Montana

Lois Olsen, USDA Forest Service, Northern Region, Helena National Forest, Helena, Montana

Dan Svoboda, USDA Forest Service, Northern Region, Beaverhead National Forest, Dillon, Montana

Richard Sounders, USDA Forest Service, Northern Region, Lewis and Clark National Forest, Great Falls, Montana

Henry Shovic, USDA Forest Service, Northern Region, Gallatin National Forest, Bozeman, Montana

Jim Shelden, USDA Forest Service, Northern Region, Missoula, Montana

Mapping of Intermountain Region:

John Lott, USDA Forest Service, Intermountain Region, Caribou National Forest, Pocatello, Idaho

Gary Jackson, USDA Forest Service, Intermountain Region, Salmon-Challis National Forest, Salmon, Idaho

Cliff Keene, USDA Forest Service, Intermountain Region, Salmon-Challis National Forest, Salmon, Idaho

Falma Moye, USDA Forest Service, Intermountain Region, Salmon-Challis National Forest, Salmon, Idaho

Leah Juarros, USDA Forest Service, Intermountain Region, Boise National Forest, Boise, Idaho

Steven Spencer, USDA Forest Service, Intermountain Region, Salmon-Challis National Forest, Salmon, Idaho

Suzanne Inglis, USDA Forest Service, Intermountain Region, Boise National Forest, Boise, Idaho

Rod Jorgensen, USDA Forest Service, Intermountain Region, Payette National Forest, McCall, Idaho

Debbie Bumpus, USDA Forest Service, Intermountain Region, Sawtooth National Forest, Twin Falls, Idaho

Randy Davis, USDA Forest Service, Intermountain Region, Bridger-Teton National Forest, Jackson, Wyoming

Terry Svalberg, USDA Forest Service, Intermountain Region, Bridger-Teton National Forest, Jackson, Wyoming

Don Fallon, USDA Forest Service, Intermountain Region, Bridger-Teton National Forest, Jackson, Wyoming

Duane Monte, USDA Forest Service, Intermountain Region, Targhee National Forest, St. Anthony, Idaho

D. Nelson, USDA Forest Service, Intermountain Region, Targhee National Forest, St. Anthony, Idaho

Terry Bowerman, USDA Forest Service, Intermountain Region, Targhee National Forest, St. Anthony, Idaho

Terry Craigg, USDA Forest Service, Intermountain Region, Targhee National Forest, St. Anthony, Idaho

Jim Dorr, USDA Forest Service, Intermountain Region, Targhee National Forest, St. Anthony, Idaho

Mapping of Pacific Northwest Region:

Duane Lammers, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Joe Bailey, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Ken Radek, USDA Forest Service, Pacific Northwest Region, Okanogan National Forest, Okanogan, Washington

Carl Davis, USDA Forest Service, Pacific Northwest Region, Wenatchee National Forest, Wenatchee, Washington

Gary Alvarado, USDA Forest Service, Pacific Northwest Region, Wenatchee National Forest, Wenatchee, Washington

Mike Andler, USDA Forest Service, Pacific Northwest Region, Wenatchee National Forest, Wenatchee, Washington

Howard Banks, USDA Forest Service, Pacific Northwest Region, Wenatchee National Forest, Wenatchee, Washington

Claudie Narcisco, USDA Forest Service, Pacific Northwest Region, Wenatchee National Forest, Wenatchee, Washington

Terry Lillybridge, USDA Forest Service, Pacific Northwest Region, Wenatchee National Forest, Wenatchee, Washington

Larry Chitwood, USDA Forest Service, Pacific Northwest Region, Deschutes National Forest, Bend, Oregon

Karen Bennett, USDA Forest Service, Pacific Northwest Region, Deschutes National Forest, Bend, Oregon

Carrie Gordon, USDA Forest Service, Pacific Northwest Region, Ochoco National Forest, Prineville, Oregon

Dave Wnzel, USDA Forest Service, Pacific Northwest Region, Fremont National Forest, Lakeview, Oregon

Bradley Smith, USDA Forest Service, Pacific Northwest Region, Deschutes National Forest, Bend, Oregon

Bill Hopkins, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Charlie Johnson, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Jim David, USDA Forest Service, Pacific Northwest Region, Ochoco National Forest, Prineville, Oregon

Jim Chamberlin, USDA Forest Service, Pacific Northwest Region, Gifford Pinchot National Forest, Vancouver, Washington

Kim Clarkin, USDA Forest Service, Pacific Northwest Region, Colville National Forest, Colville, Washington

Jay Berabe, USDA Forest Service, Pacific Northwest Region, Colville National Forest, Colville, Washington

Bud Kovalchik, USDA Forest Service, Pacific Northwest Region, Colville National Forest, Colville, Washington

Bert Wasson, USDA Forest Service, Pacific Northwest Region, Colville National Forest, Colville, Washington

Paula Barreras, USDA Forest Service, Pacific Northwest Region, Colville National Forest, Colville, Washington

Mapping of Northeast California:

P. VanSusteren, USDA Forest Service, Pacific Southwest Region, Shasta-Trinity National Forest, Redding, California

T. Laurent, USDA Forest Service, Pacific Southwest Region, Klamath National Forest, Yreka, California

Mapping of Northwest Wyoming:

Kent Houston, USDA Forest Service, Rocky Mountain Region, Shoshone National Forest, Cody, Wyoming

Jerry Freeouf, USDA Forest Service, Rocky Mountain Region, Lakewood, Colorado

Mapping of BLM land:

Terry Aho, Natural Resources Conservation Service, Washington

Thor Thorson, Natural Resources Conservation Service, Oregon

Chuck Gordon, Natural Resources Conservation Service, Montana

Harold Maxwell, Natural Resources Conservation Service, Idaho

Harley Noe, Natural Resources Conservation Service, Idaho

Geological information throughout the basin:

Tom Frost, U.S. Geological Survey, Spokane, Washington

Mapping of Bureau of Land Management areas:

Clif Fanning, BLM Oregon State Office, Portland, Oregon

Bill Volk, BLM Montana State Office, Billings, Montana

Vito Celberti, BLM Montana State Office, Billings, Montana

Nancy Ketrenos, BLM Montana State Office, Billings, Montana

Paul Seronko, BLM Lower Snake River District, Boise Field Office, Boise, Idaho

Preparation of preliminary maps was by contractor:

Herb Holdorf

John Arnold

Contributors to landtype association mapping:

Project coordinators:

John Nesser, USDA Forest Service, Northern Region, Missoula, Montana

Gary Ford, USDA Forest Service, Northern Region, Missoula, Montana

Geographic information systems:

Cathy Maynard, USDA Forest Service, Northern Region, Missoula, Montana

Duane Lund, NRIS, Montana State Library, Missoula, Montana

Kristina Gurrieri, NRIS, Montana State Library, Missoula, Montana

Cartographic support:

Ted Nyquist, USDA Forest Service, Northern Region, Missoula, Montana

Mapping of the eastern Washington, eastern Oregon and southern Idaho was done by the following contractors:

Herb Holdorf

Norm Bare

Contributors to soil productivity expert panel:

Bob Meurisse, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

John Nesser, USDA Forest Service, Northern Region, Missoula, Montana

Tom Collins, USDA Forest Service, Intermountain Region, Ogden, Utah

Jim Clayton, USDA Forest Service, Intermountain Research Station, Boise, Idaho

Russ Graham, USDA Forest Service, Intermountain Research Station, Moscow, Idaho

Al Harvey, USDA Forest Service, Intermountain Research Station, Moscow, Idaho

Debbie Page-Dumroese, USDA Forest Service, Intermountain Research Station, Moscow, Idaho

Bill Ypsilantis, Bureau of Land Management, Coeur d'Alene, Idaho

Cliff Fanning, Bureau of Land Management, Oregon/Washington State Office, Portland, Oregon

Gary Ford, USDA Forest Service, Northern Region, Missoula, Montana

Geographic information systems:

Gini Stoddard, USDA Forest Service, Interior Columbia Basin Ecosystem Management Project, Walla Walla, Washington

Contributors to broad-scale potential natural vegetation mapping:

Workshop coordination and facilitation:

Patrick Bourgeron, The Nature Conservancy, Boulder, Colorado

Lisa Engelking, The Nature Conservancy

Marion Reid, The Nature Conservancy

Gary Ford, USDA Forest Service, Northern Region, Missoula, Montana

Jim Menakis, USDA Forest Service, Northern Region, Fire Sciences Laboratory, Missoula, Montana

Mark Jensen, USDA Forest Service, Northern Region, Missoula, Montana

Vegetation classification by moisture and temperature gradients:

Patrick Bourgeron, The Nature Conservancy, Boulder, Colorado

Lisa Engelking, The Nature Conservancy

Steve Cooper, Montana Natural Heritage Program

Bob Mosely, Idaho Conservation Data Center

Jimmy Kagan, Oregon Natural Heritage Program

Rex Crawford, Washington Natural Heritage Program

Bradley Smith, USDA Forest Service, Pacific Northwest Region, Deschutes National Forest, Bend, Oregon

Bill Hopkins, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Charlie Johnson, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Susan Boudreau, USDA Forest Service, Intermountain Region, Payette National Forest, McCall, Idaho

Bill Rush, USDA Forest Service, Intermountain Region, Boise National Forest, Boise, Idaho

Ken Brewer, USDA Forest Service, Northern Region, Flathead National Forest, Kalispell, Montana

Larry Walker, USDI Bureau of Land Management, Oregon State Office, Portland, Oregon

Cheryl McCaffrey, USDI Bureau of Land Management, Oregon State Office, Portland, Oregon

Steve Jirik, USDI Bureau of Land Management, Idaho State Office, Boise, Idaho

Contributors to Broad-Scale Potential Natural Vegetation Mapping:

Geographic information systems:

Jim Menakis, USDA Forest Service, Northern Region, Fire Sciences Laboratory, Missoula, Montana

Bob Keane, USDA Forest Service, Northern Region, Fire Sciences Laboratory, Missoula, Montana

Don Long, USDA Forest Service, Northern Region, Fire Sciences Laboratory, Missoula, Montana

Marty Beck, USDA Forest Service, Northern Region, Fire Sciences Laboratory, Missoula, Montana

Janice Garner, USDA Forest Service, Northern Region, Lolo National Forest, Missoula, Montana

Cam Johnston, USDA Forest Service, Northern Region, Fire Sciences Laboratory, Missoula, Montana

Development of Elevation, Aspect and Slope Rules for Potential Vegetation Types:

Vic Applegate, USDA Forest Service, Northern Region, Lolo National Forest, Missoula, Montana

John Arnold, Contractor

Dave Atkins, USDA Forest Service, Northern Region, Lolo National Forest, Missoula, Montana

Steve Bateman, USDA Forest Service, Northern Region, Nez Perce National Forest, Grangeville, Idaho

Rita Beard, USDA Forest Service, Northern Region, Gallatin National Forest, Bozeman, Montana

Doug Berglaund, USDA Forest Service, Northern Region, Flathead National Forest, Kalispell, Montana

Mike Boltz, USDI Bureau of Land Management, Idaho State Office, Boise, Idaho

Jo Booser, USDA Forest Service, Pacific Northwest Region, Deschutes National Forest, Bend, Oregon

Susan Boudreau, USDA Forest Service, Intermountain Region, Payette National Forest, McCall, Idaho

Ken Brewer, USDA Forest Service, Northern Region, Flathead National Forest, Kalispell, Montana

Lew Brown, USDI Bureau of Land Management, Idaho State Office, Boise, Idaho

Lee Clark, USDA Forest Service, Northern Region, Clearwater National Forest, Orofino, Idaho

Steve Cooper, Montana Natural Heritage Program

Jim Cornwell, Natural Resources Conservation Service, Idaho

Rex Crawford, Washington Natural Heritage Program

Lynn Danly, USDI Bureau of Land Management, Idaho State Office, Boise, Idaho

Randy Davis, USDA Forest Service, Intermountain Region, Bridger-Teton National Forest, Jackson, Wyoming

Ted Demetriades, USDA Forest Service, Intermountain Region, Payette National Forest, McCall, Idaho

Bruce Easton, USDI Bureau of Land Management, Idaho State Office, Boise, Idaho

Sue Ferguson, USDA Forest Service, Pacific Northwest Region, Forestry Sciences Lab, Seattle, Washington

Jean Findley, USDI Bureau of Land Management, Oregon State Office, Portland, Oregon

Steve Fletcher, USDA Forest Service, Pacific Northwest Region, Wallowa-Whitman National Forest, Baker City, Oregon

Dennis Froeming, Natural Resource Conservation Service, Montana

Steve Gibson, USDA Forest Service, Pacific Northwest Region, Wallowa-Whitman National Forest, Baker City, Oregon

Dave Hayes, USDA Forest Service, Northern Region, Nez Perce National Forest, Grangeville, Idaho

Stephen Hiebert, USDA Forest Service, Pacific Northwest Region, Malheur National Forest, John Day, Oregon

Brian Hockett, USDI Bureau of Land Management, Montana State Office, Billings, Montana

Steve Holzman, U.S. Fish & Wildlife, Portland, Oregon

Bill Hopkins, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Ed Horn, USDI Bureau of Land Management, Oregon State Office, Portland, Oregon

Dent Houston, USDA Forest Service, Rocky Mountain Region, Shoshone National Forest, Cody, Wyoming

Gary Jackson, USDA Forest Service, Intermountain Region, Salmon-Challis National Forest, Salmon, Idaho

Harry Jageman, USDA Forest Service, Northern Region, Clearwater National Forest, Orofino, Idaho

Darwin Jeppesen, USDI Bureau of Land Management, Idaho State Office, Boise, Idaho

Steven Jirik, USDI Bureau of Land Management, Idaho State Office, Boise, Idaho

Charlie Johnson, USDA Forest Service, Pacific Northwest Region, Portland, Oregon

Rod Jorgenson, USDA Forest Service, Intermountain Region, Payette National Forest, McCall, Idaho

Jimmy Kagan, Oregon Natural Heritage Program

Todd Keller-Wolf, California Natural Diversity Database

Lou Kuennen, USDA Forest Service, Northern Region, Kootenai National Forest, Libby, Montana

Larry Laing, USDA Forest Service, Northern Region, Helena National Forest, Helena, Montana

Scott Lambert, Natural Resources Conservation Service, Washington

Jean Lavell, USDA Forest Service, Northern Region, Helena National Forest, Helena, Montana

Dean Leavell, USDA Forest Service, Northern Region, Kootenai National Forest, Libby, Montana

Terry Lillybridge, USDA Forest Service, Pacific Northwest Region, Wenatchee National Forest, Wenatchee, Washington

John Lott, USDA Forest Service, Intermountain Region, Caribou National Forest, Pocatello, Idaho

Maria Mantas, USDA Forest Service, Northern Region, Flathead National Forest, Kalispell, Montana

Dave Marben, USDA Forest Service, Intermountain Region, Boise National Forest, Boise, Idaho

Harold Maxwell, Natural Resources Conservation Service, Idaho

GLOSSARY

aeolian - (a) Pertaining to the wind; especially said of such deposits as loess and dune sand, of sedimentary structures such as wind-formed ripple marks, or of erosion and deposition accomplished by the wind. (b) Said of the active phase of a dune cycle, marked by diminished vegetal control and increased dune growth.

air mass - A widespread body of air that is approximately homogeneous in its horizontal extent, particularly with reference to temperature and moisture distribution. In addition, the vertical temperature and moisture variations are approximately the same over its horizontal extent

alkalinity - The power of a solution to neutralize hydrogen ions (H+).

alluvium - A general term for clay, silt, sand, gravel, or similar unconsolidated detrital material deposited during comparatively recent geologic time be a stream or other body of running water as a sorted or semi-sored sediment in the bed of the stream.

anticyclone - A closed circulation usually around a center of high atmospheric pressure. The terms anticyclone and high often are used interchangeably. Anticyclonic flow is clockwise in the northern hemisphere

biogeography - The study of the geographical distributions of organisms, their habitats (ecological biogeography) and their historical and biological factors which produce them (historical biogeography); chorology, geonemy.

biophysical - The combination of biological and shysical components in an ecosystem.

biosphere - the global ecosystem; that part of the Earth and atmosphere capable of supporting living organisms.

biotic - Living; relating to life or specific life conditions.

chinook winds - Chinook is a local name for foehn wind. Originally named for winds off the Rocky Mountains but generally applied across the western U.S.

climate - The prevailing weather or long-term manifestations of weather

climate division - Each U.S. state has been subdivided into climatic divisions. The divisional boundaries are defined mainly by drainage basins or major crops and may or may not delineate areas of climatological homogeneity.

colluvium - A general term applied to any loose, heterogeneous, and incoherent mass of soil material and/or rock fragments deposited by rainwash, sheetwash, or slow continuous downslope creep, usually collecting at the base of gentle slopes or hillsides.

continental air mass - A type of air whose characteristics are developed over a large land area and which, therefore, has the basic continental characteristic of relatively low moisture content.

convection - In meteorology, atmospheric motions that are predominantly vertical, resulting in vertical transport and mixing of atmospheric properties

Convective precipitation - Precipitation from convective clouds; generally considered to be synonymous with showers

Cooperative Observer Network (COOP) - A network of unpaid observers who maintain meteorological stations for the National Weather Service. The usual instruments of observation are maximum and minimum thermometers and a non-recording precipitaion gage.

cyclone - A closed circulation usually around a center of low atmospheric pressure. The terms cyclone and low often are used interchangeably. Also, because cyclones nearly always are accompanied by inclement (often destructive) weather, they frequently are referred to simply as storms. Cyclonic flow is counter-clockwise in the northern hemisphere.

down burst - A strong win characterized by a sudden onset and a duration on the order of minutes. Associated with the air movement around thunderstorms.

ecosystem - An area of any size with an association of physical and biological components so organized that a change in any one component will bring about a change in the other components and the operation of the whole system.

El Niño - A warm-water current that flows southward along the coast of Ecuador during the Christmas season (the name refers to the Christ child). The negative phase of an El Niño is called a La Niña.

El Niño Southern Oscillation (ENSO) - The collective link between El Niño and the Southern Oscillation that has climatic effects throughout the Pacific region and sometimes elsewhere. It occurs every five to eight years when the prevailing trade winds weaken and the equatorial countercurrent strengthens. This causes warm survace waters, normally diven westward by the wind, to form a deep layer off Indonesia and flow eastward to overly the cold waters of the Peru current.

equivalent potential temperature - The termperature that a parcel of air would be if it were brought from its inital state to a pressure level of 1,000 mb (near standard sea level), without transferring heat or mass across its boundaries. It allows analysis of air mass temperatures by minimizing the effects of changing altitude and changing water phases.

evapotranspiration - The combined processes by which water is transferred from the earth's surface to the atmosphere; evaporation of liquid or solid water plus transpiration from plants.

floodplain - lowland bordering a stream or river onto which the flow spreads at flood stage

front - The interface between tow air masses of different density. Because the termperature distribution is the most important regulator of atmospheric density, a front most often separates air masses of different temperature. Changing wind directions, moisture content, and atmospheric pressure patterns also can distinguish a front.

frontal zone - The transition zone between two air masses of differenct density.

gap winds - Winds that are channeled and usually accelerated through a gap between mountains.

geoclimatic - The combination of geologic and climatic components in an ecosystem.

greenhouse effect - The heating effect exerted by the atmosphere upon the earth by virtue of the fact that the atmosphere (mainly its water vapor) absorbs and remits infrared radiation. The shorter wavelengths of solar radiation are transmitted rather freely through the atmosphere to be absorbed at the earth's surface. The earth then remits this as long-wave (infrared) terrestrial radiation, a portion of which is absorbed by the atmosphere and again emitted -- some back downward to the earth's surface.

greenhous gas - Atmospheric gases that are nearly transparent to solar radiation but almost opaque to longwave (terrestrial) radiation. These include water vapor, carbon dioxided, tropospheric ozone, nitrous oxide, methane, chlorofluorocarbons, halocarbons, and precursors of any of these gases.

hierarchy - A general integrated system comprising two or more levels, the higher controlling to some extent the activities of the lower levels; a series of consecutively subordinate categories forming a system of classification.

Holocene - most recent geological epoch; the approximately 10,000 years since the last major continental glaciation.

humidity - Some measure of water vapor content of air. Typically measured as dew point temperature or relative humidity.

hydrography - The scientific description and analysis of the physical conditions, boundaries, flow, and related characteristics of surface waters, as ocianslakes, and rivers; the mapping of bodies of water; a book on hydrography.

intermontane - Situated between or surrounded by mountains, mountain ranges, or mountainous regions; for example the great Basin of western U.S.; between the Sierra Nevada and the Wasatch Mountains.

inversion (temperature) - A layer of air in which temperature increases with height. It is extremely stable.

jet stream - Relative strong winds concentrated within a narrow stream in the atmosphere. While this term may be applied to any such stream, regarless of direction (including vertical), it is coming more and more to mean only the quasi-horizontal jet stream of maximum winds imbedded in the mid-latiture westerlies, and concentrated at an altitude of about 10 km. Two jets are distinguished, the polar jet and subtropical jet.

lacustrine - (a) Pertaining to, produced by, or formed in a lake or lakes, such as "lacustrine sands" deposited on the bottom of a lake, or a "lacustine terrace" formed along its margin. (b) Growing in or inhabiting lakes, such as "lacustrine fauna". (c) Said of a region characterized by lakes, such as a "lacustrine desert" containing the remnants of numerous lakes that are now dry.

landscape - A heterogeneous land area with interacting ecosystems that are repeated in similar form throughout.

loess - A widespread, homogeneous, commonly nonstratified, porous, friable, slightly coherent, usually highly calcareous, fine-grained blanket deposit (generally less than 30 m thick), consisting predominantly of silt with subordinate grain sizes ranging from clay to fine sand.

marine air mass - A type of air whose characteristics are developed over an extensive water surface and which, therefore, has the basic maritime quality of high moisture content in at least its lowere levels. Also called maritime air.

marine push - A term applied to the sudden transition between warm, dry conditions to cool, moist conditions as marine arir displaces continental air. In the Pacific Northwest a marine push often occurs after a themal low moves from the cost to the interior. While the low is near the coast, dry easterly surface winds prevail. Once inland, east of the Cascade mountains, the pressure gradients associated with the thermal low cause westerly surface winds to draw marine air in the Columbia River Basin.

meridional flow - A type of atmospheric circulation pattern in which the meridional (north and south) component of motion is unusually pronounced. The accompanying zonal component is usually weaker than normal. Meridional flow is characterized by high amplitude troughs and ridges.

mesoscale - The horizontal scale of atmospheric motion typically between 1 and 100 kilometers where vertical motions become important. Usually less than the size of a typical cyclonic strom but greater than the size of a thunderstorm.

metasediment - A sediment or sedimentary rock that shows evidence of having been subjected to metamorphism.

microrelief - (a) Local, slight irregularities of a land surface, including such features as low mounds, swales, and shallow pits, generally about a meter indiameter, and causing variations amounting to no more than 3 m. (b) Relief features that are too small to show on a topographic map, such as gullies, mounds, boulders, pinnacles, or other features less than 60 m in diameter and less than 6 m in elevation, in an area for which the topographic map has a scale of 1:50,000 or smaller and a contour interval of 3 m (10 ft) or larger.

mixing height - The height at which the atmosphere becomes stable or the height of a ground-based stable layer. An air parcel near the earth's surface can be naturally buoyant and rise vertically until it reaches a level where surrounding air is cooler than the parcel. Then it stops rising. Mixing height is the level at which air stops rising or stops vertical mixing.

normal - In meteorology, the average value of a meteorological element over any fixed period of years that is recognized as standard for the country and element concerned. In the Unitied States, the National Climatic Data Center calculates averages over 30-year periods to describe climate normals. These are recalculated every decade. The mosat recent normals at the time of this writing are for the period 1961-1990.

Pacific air mass - A marine air mass that developed over the Pacific Ocean.

Pacific North American (PNA) index - Describes the strength of the ridge-trough-ridge pattern of upper level flow over North America. Best defined during winter. Positive indices indicate a strong low centered near the Aleutian islands, a strong ridge in the eastern Pacific an western United States, and a deep trough in the eastern United States. Negative indices indicate a more zonal flow pattern with low amplitude ridges and troughs.

paleo-climate - Climate that is reconstructed from proxy data like tree rings, fossil pollen, deep sea sediments, glacier fluctuations, and ice cores. In the western U.S. this usually means any climate prior to about 1895.

palustrine - pertaining to material growing or deposited in a marsh or marsh-like environment.

periglacial - (a) Said of the processes, conditions, areas, climates, and topographic features at the immediate margins of former and exisitng glaciers and ice sheets, and influenced by the cold temperature of the ice. (b) By extension, said of an environment in which frost action is an important factor, or of phenomena induced by a periglacial climate beyond the periphery of the ice.

pit mounds - uprooting of trees creates pits and mounds that differ in several properties from soilds that have not been overturned. Pits have more litter and standing water and mounds have less than do other soils.

physiography - pertaining to geographical features of the Earth's surface [LB]

pluvial - [Clim] Said of a climate characterized by relatively high precipitation, or of the time interval during which such a climate prevailed. Formerly equated with the glacial stage of the Quaternary glacial/interglacial sequence, pluvial intervals are now regarded more as transitional, or, in low latitudes, as typical of interglacials. [Geomorph] Said of a geologic episode, change, process, deposit, or feature resulting from the action or effects of rain; such as pluvial denudation, a landslide, or gully erosion and the consequent spreading-out of the eroded material below. The term sometimes includes the fluvial action of rainwater flowing in a stream channel, especially in the channel of an ephemeral stream.

polar jet stream - A jet stream associated with the plar front. It fluctuates around 40 degrees latitude over the western U.S. during winter and areound 60 degrees latitude during summer.

potential natural vegetation - The vegetation that would exist today if man were removed from the scene and if the plant succession after his removal were telescoped into a single moment. The time compression eliminated the effects of future climatic fluctuations, while the effects of man's earlier activities are permitted to stand. The maps and description s of potential natural vegetation developed by Kuchler (1964) for the 48 conterminous States are among the most widely used.

pressure level - A level of altitude at which the atmospheric pressure is everywhere equal at a given instant.

province - An ecological unit in the ecoregion planning and analysis scale of the National Hierarchical Framework corresponding to subdivisions of a Division that conform to climatic subzones controlled mainly by continental weather patterns.

radiosonde - A balloon-borne instrument for the simultaneous measurement and transmission of meteorological data.

radiosonde observation (RAOB) - An evaluation in terms of temperature, relative humidity, and pressure aloft, of radio signals received from a balloon-borne radiosonde; the height of each mandatory and significant pressure level of the observation is computed from these data.

rain-on-snow flood - A flood caused by rain falling on an existing snowcover. Usually of greater magnitude than floods caused by pure snowmelt or by floods caused by pure rainfall. The effect is most significant when sallow snowcover exists at relatively low elevations. Deep snowcover at higher elevations can absorb rainwater.

rain shadow - A region on the lee side of a mountain or maountain range where precipitation is noticeably less than on the windward side.

ridge - In meteorology, an elongated areas of relatively high atmospheric pressure, almost always associated with and most clearly identified as an area of maximum anticyclonic curvature of wind flow.

section - An ecological unit in the subregion planning and analysis scale of the National Hierarchical Framework corresponding to subdivisions of a province having broad areas of similar geomorphic process, stratigraphy, geologic origin, drainage networks, topography, and regional climate. Such areas are often inferred by relating geologic maps to potential natural vegetation groupsings as mapped by Kuchler (1964).

significant level - In a radiosonde observation, a level (other than a mandatory level) for which values of pressure, temperature, and humidity are reported because temperature and/or moisture content data at that level are sufficiently important or unusual to warrant the attention of a forecaster, or they are required for the reasonably accurate reproduction of the radiosonde observation.

slope winds- Local diurnal winds that occur on all sloping surfaces. During the day, air rised as the ground is heated by sunshine so winds generally flow upslope. During night, air cools and sinks so winds generally flow downslope.

snow water equivallent (SWE) - The depth of water that would result from the melting of the snow pack or of a snow sample. Thus, the water equivalent of a new snowfall is the same as the amount of precipitation represented by that snowfall.

snowfall - Precipitating snow. Usually measured as depth of snow accumulating on a plate that is cleaned after each observation. Cooperative observers usually measure snowfall once each day and first-order station observers usually measure once each hour. More frequent measurements produce higher values of snowfall than less frequent measurements because snow settles and decreases volume after falling. New sensors are becomin available, which can measure the water content of snow as it is falling, that may prevent the disparities caused by variable measurement frequency.

Southern Oscillation (SO) - A fluctuation of the intertropical atmospheric circulation, in particular in the Indian and Pacific Oceans, in which air moves between the southeast Pacific subtropical high and the Indonesian equatorial low, driven by the temperature difference between the two areas. The general effect is that, when pressure is high over the eastern Pacific ocean, it tends to be low in the eastern Indian Ocean, and vice versa. The phenomenon is strongly linked to El Niño.

stable air - Air in which small disturbances do not grow; vertical motions are small. Stable air commonly causes or enhances inversions. In a dry atmosphere, if air temperatures decrease with increasing altitude at a rate less than 9.8° C per kilometer it is stable.

subregion - A scale of planning and analysis in the National Hierarchical Framework that has applicability for strategic, multi-forest, statewide, and multi-agency analysis and assessment. Subregions include Section and Subsection ecological units.

subsection - An ecological unit in the subregion planning and analysis scales of the National Hierarchical Framework corresponding to subdivisions of a Section into areas with similar surficial geology, lithology, geomorphic process, soil groups, subregional climate, and potential natural communities.

synoptic - In meteorology, the use of meteorological data obtained simultaneously over a wide area for the purpose of presenting a comprehensive and nearly instantaneous picture of the state of the atmosphere. Therefore, synoptic is synonymous to simultaneity.

synoptic weather - Weather that can be described with synoptic data, usually on the scale of a typical cyclonic storm over a period of a day or two.

thermal low (or heat low) - An area of low atmospheric pressure (a low) due to high temperatures caused by intensive heating at the earth's surface. Thermal lows are common to the continental subtropics in summer. A thermal low often develops in California's interior valley and can migrate northward into Oregon and Washington. If it stays west of the Cascades, it can cause or enhance easterly surface winds in western Oregon and Washington. If it moves from west to east of the Cascades it can create a "marine push," bringing cool marine air into the Columbia River Basin. Strong marine pushes can cause strong thunderstorms to develop over the interior valleys and into the Snake River Plain.

trough - In meteorology, an elongated area of relatively low atmospheric pressure; the opposite of a ridge.

unstable air - Air in which small disturbance can grow; vertical motions can be large. Commonly associated with thunderstorms. In a dry atmosphere, if air temperatures decrease with increasing altitude at a rate more than 9.8° C per kilometer it is unstable.

upper-air - Generally applies to the atmosphere above the 850 mb pressure level.

zonal flow (zonal circulation) - In meteorology, the flow of air along a latitude circle; the latitudinal (east or west) component of existing flow. Usually having low amplitude troughs and ridges.

APPENDIX 2A

Listing of Biophysical Environment Variable and Interpretations Attributed to Subbasins and Subwatersheds for Analysis

Field Code: ERO

Field Description: This field contains the surface erosion hazard coefficient for each hydrologic unit (4th- or 6th-field HUC). The logic and methodology outlined in U. S. Environmental Protection Agency (1980) was modified for use in broad-scale assessments. Factors used include slope, rainfall intensity, surficial geology, and vegetation cover.

Field Code: BASEERO

Field Description: This field contains the base surface erosion hazard coefficient, without the ameliorating effect of vegetation, for each hydrologic unit (4th- or 6th-field HUC). The logic and methodology outlined in U. S. Environmental Protection Agency (1980) was modified for use in broad-scale assessments. Factors used include slope, rainfall intensity, and surficial geology. (In this context BASE means surface erosion rates with no vegetation cover.)

Field Code: STE

Field Description: This field contains a measure of the physical characteristics of the landscape involved with the potential delivery of sediment to streams for each hydrologic unit (4th- or 6th-field HUC). Factors used include slope, drainage density, and surficial geology.

Field Code: SED

Field Description: This field contains the sediment delivery hazard coefficient for each hydrologic unit (4th- or 6th-field HUC). Factors used include surface erosion hazard (ERO) and sediment transport efficiency (STE).

Field Code: BASESED

Field Description: This field contains the base sediment delivery hazard coefficient, without the ameliorating effect of vegetation, for each hydrologic unit (4th- or 6th-field HUC). Factors used include the base surface erosion hazard (BASEERO) and sediment transport efficiency (STE). (In this context, BASE means surface erosion rates with no vegetation cover.)

Field Code: MASS

Field Description: This field contains the slumping (i.e., rotational slumps) hazard rating coefficient for each hydrologic unit (4th- or 6th-field HUC). The logic and methodology outlined in U. S. Environmental Protection Agency (1980) was modified for use in broad-scale assessments. Factors used include slope, soil properties, and precipitation.

Field Code: DEBRIS

Field Description: This field contains the debris avalanche (i.e., translational slump) hazard rating coefficient for each hydrologic unit (4th- or 6th-field HUC). The logic and methodology outlined in U. S. Environmental Protection Agency (1980) was modified for use in broad-scale assessments. Factors used include slope and precipitation.

Field Code: IS_FLOW

Field Description: This field contains the on-site hazard rating for changes in channel morphology resulting from increased flow and/or sediment for each hydrologic unit (4th- or 6th-field HUC). The hazard rating is for the dominant stream channel types in an area, using the stability ratings described by Rosgen (1994).

Field Code: DS_FLOW

Field Description: This field contains the on-site hazard rating for changes in channel morphology resulting from decreased flow and/or sediment for each hydrologic unit (4th- or 6th-field HUC). The hazard rating is for the dominant stream channel types in an area, using the stability ratings described by Rosgen (1994).

Field Code: BANK

Field Description: This field contains the average streambank erosion hazard rating for each hydrologic unit (4th- or 6th-field HUC). The hazard rating is for the dominant stream channel types in an area, using the stability ratings described by Rosgen (1994).

Field Code: VEG

Field Description: This field contains the average vegetation influence rating for the dominant stream channel types in each hydrologic unit (4th- or 6th-field HUC), using the stability ratings described by Rosgen (1994).

Field Code: RECOVERY

Field Description: This field contains the average stream channel recovery potential rating for the dominant stream channel types in each hydrologic unit (4th- or 6th-field HUC), using the recovery ratings described by Rosgen (1994).

Field Code: MWSI

Field Description: This field contains an index value which rates the relative sensitivity of each hydrologic unit (4th- or 6th-field). This sensitivity index is an overall rating that combines the general potential for sediment delivery with the average potential for stream channels to recover from disturbance. MWSI is a relative index that is derived using the CBASESED_B and RECOVERY fields calculated as: (CBASESED_B + [100 - RECOVERY]), where CBASESED_B is the base sediment delivery hazard/ basin cumulative frequency, which is a field containing the cumulative frequency distribution (expressed as a percentile) of the base sediment delivery hazard coefficient, without the ameliorating effect of vegetation, for each hydrologic unit (4th or 6th field). Factors used include the base surface erosion hazard (BASEERO) and sediment transport efficiency (STE). (In this context, BASE means surface erosion rates

with no vegetation cover). The cumulative frequency is relative to all HUCs within the ICRB. And where RECOVERY is the average recovery potential rating, which is a field containing the average stream channel recovery potential rating for the dominant stream channel types in each hydrologic unit (4th or 6th field), using the recovery ratings described by Rosgen (1994). The formula uses (100 - RECOVERY) to make the numerical expression of sensitivity consistent; hence a "high" recovery potential value would not cancel out a "high" base sediment delivery hazard coefficient value.

Field Code: ROADHAZ

Field Description: This field contains the relative road erosion hazard rating for each hydrologic unit (4th- or 6th-field). This rating is based on the relative erodibility of surface material as defined by lithology, calculated as: SUM (percent of each lithology *RE for each lithology).

Field Code: *MINES

Field Description: This field contains a categorical variable (Yes or No) indicating whether a 6th-field hydrologic unit has mining activity. Mining activity was derived from USGS point data and is defined as a HUC that has TYPE = placer, surface, or surf-underground and STATUS = devel. (This base layer is documented elsewhere.) This field is only in the table for 6th-field watersheds, H6INTERP.

Field Code: *CROPLAND

Field Description: This field contains a categorical variable (Yes or No) indicating whether a 6th-field hydrologic unit has substantive agricultural activity. Agricultural activity was derived from the broad-scale VEG data and is defined as a HUC that has cropland cover-type greater than or equal to 15 percent. (This base layer is documented elsewhere.) This field is only in the table for 6th-field watersheds, H6INTERP.

Field Code: *DAMS

Field Description: This field contains a categorical variable (Yes or No) indicating whether a 6th-field hydrologic unit has dams present. Dams were derived from point data from the aquatics staff. (This base layer is documented elsewhere.) This field is only in the table for 6th-field watersheds, H6INTERP.

Field Code: *ROAD_CLASS

Field Description: This field contains a categorical variable (High, Moderate, or Low) indicating the road density class of each 6th-field hydrologic unit. Road density classes were derived using the five density classes from the landscape ecology staff and collapsing them to three by combining Very Low and Low (into Low) and High and Extremely High into High. (This base layer is documented elsewhere.) This field is only in the table for 6th-field watersheds, H6INTERP.

Field Code: *RDSENSITIV

Field Description: This field contains a road sensitivity index value derived using a combination of the basinwide cumulative frequency distributions of sediment delivery hazard (CSED_B), increased flow and/or sediment hazard rating/on-site (CISFLOW_B), and the road erosion hazard (CROADHAZ_B) calculated as: (CSED_B = CISFLOW_B + CROADHAZ_B)/3. This value is then reordinated into a cumulative frequency distribution (expressed as a percentile). This field is only in the table for 6th-field watersheds, H6INTERP.

Field Code: **MASTER_LIM

Field Description: This field contains a categorical variable (Yes or No) indicating the hydrologic integrity of a 4th-field hydrologic unit that may be adversely affected by one or more factors. The factors considered include mining activity, agricultural activity, roading, and dams. The field is "Yes" if the percentage of 6th-field hydrologic units with extensive road systems in sensitive areas within a 4th-field hydrologic unit (**PCT_ROAD), or the percentage of 6th-field hydrologic units containing dams within a 4th-field hydrologic unit (**PCT_DAM), or the percentage of 6th-field hydrologic units with agricultural activity within a 4th-field hydrologic unit (**PCT_CROP), or the percentage of 6th-field hydrologic units with mining activity within a 4th- field hydrologic unit (**PCT_MINES) is equal to or greater than 15 percent. This field is only in the table for 4th-field watersheds, H4INTERP. "Yes" if (**PCT_ROAD) or (**PCT_DAM) or (**PCT_CROP) or (**PCT_MINES) is >= 15 percent.

Field Code: **HYDR_DIST

Field Description: This field contains an index value for hydrologic disturbance that was derived using factors relating to hydrologic integrity. The factors considered include mining activity, agricultural activity, roading, and dams. The index value is calculated by summing the percentage of 6th-field hydrologic units with extensive road systems in sensitive areas within a 4th-field hydrologic unit (**PCT_ROAD), and the percentage of 6th-field hydrologic units containing dams within a 4th-field hydrologic unit (**PCT_DAM), and the percentage of 6th-field hydrologic units with agricultural activity within a 4th-field hydrologic unit (**PCT_CROP) and the percentage of 6th-field hydrologic units with mining activity within a 4th-field hydrologic unit (**PCT_MINES). The sum of these percentages is then distributed into cumulative frequencies (expressed as percentiles). This field is only in the table for 4th-field watersheds, H4INTERP. HYDR_DIST = cumulative frequency distribution of (**PCT_RAOD) + (**PCT_DAM) + (**PCT_CROP) + (**PCT_MINES)

Field Code: **CHYDR_INTEG_B

Field Description: This field contains an index value that rates the relative hydrologic integrity of each 4th-field hydrologic unit. It was derived using factors that relate to both hydrologic disturbance and recovery. This integrity index is an overall rating that combines the general potential for hydrologic disturbance with the average potential for stream channels to recover from disturbance; it is derived using the CHYDR_DIST_B and CRECOVERY_B fields calculated as: (100 - CHYDR_DIST_B) + (CRECOVERY_B). Where CHYDR_DIST_B is the hydrologic disturbance index value for 4th-field hydrologic units/basin cumulative frequency, which is a field containing the cumulative frequency distribution (expressed as a percentile) of the hydrologic disturbance index for each 4th-field hydrologic unit. This index value for hydrologic disturbance was derived using factors that relate to hydrologic integrity. The factors considered include mining activity, agricultural activity, roading, and dams. The index value is calculated by summing the percentage of 6th-field hydrologic units with extensive road systems in sensitive areas within a 4th-field hydrologic unit (**PCT_ROAD), and the percentage of 6th-field hydrologic units containing dams within a 4th-field hydrologic unit (**PCT_DAM), and the percentage of 6th-field hydrologic units with agricultural activity within a 4th-field hydrologic unit (**PCT_CROP) and the percentage of 6th-field hydrologic units with mining activity within a 4th-field hydrologic unit (**PCT_MINES). The sum of these percentages is then distributed into cumulative frequencies (expressed as percentiles). The cumulative frequency is relative to all HUCs within the ICRB. CHYDR_DIST_B = cumulative frequency distribution of (**PCT_ROAD) + (**PCT_DAM) + (**PCT_CROP) + (**PCT_MINES)

And where CRECOVERY_B is the average recovery potential rating/basin cumulative frequency, which is a field that contains the cumulative frequency distribution (expressed as a percentile) of the average stream channel recovery potential rating for the dominant stream channel types, in each 4th-field hydrologic unit using the recovery ratings described by Rosgen (1994). The cumulative frequency is relative to all 4th-field HUCs within the ICRB. The formula uses (100 - CHYDR_DIST_B) to make the numerical expression of integrity consistent; hence a "high" recovery potential value would not cancel a "high" hydrologic disturbance index value. The sum of these percentiles is then redistributed into cumulative frequencies (expressed as percentiles) relative to all HUCs within the ICRB. **This field is only in the table for 4th-field watersheds, H4INTWERP.

Field Code: RIP_DIST

Field Description: This field contains an index value for riparian disturbance that was derived using factors relating to riparian condition including both streambank erosion hazard ratings and the vegetation influence rating. This disturbance index is an overall rating that combines the streambank erosion hazard rating with the average vegetation influence rating; it is derived using the BANK and BEG fields calculated as: (BANK + VEG)/2. Where BANK is the average streambank erosion hazard rating, which contains the average streambank erosion hazard rating for each hydrologic unit (4th- or 6th-field). The hazard rating is for the dominant stream channel types in an area, using the stability ratings described by Rosgen (1994). And where VEG is the average vegetation influence rating, which contains the average vegetation influence rating for the dominant stream channel types in each hydrologic unit (4th- or 6th-field), using the stability ratings described by Rosgen (1994).

Field Code: RIP_INTEG

Field Description: This field contains an index value that rates the relative riparian area integrity of each 4th- and 6th-field hydrologic unit. It was derived using factors that relate to both riparian area disturbance and recovery. This integrity index is an overall rating that combines the general potential for riparian area disturbance with the average potential for stream channels to recover from disturbance; it is derived using the RIP_DIST and RECOVERY fields calculated as: (100 - RIP_DIST) + (RECOVERY). Where RIP_DIST is the hydrologic disturbance index value for 4th-field hydrologic units, which is a field containing an index value for riparian disturbance derived using factors that relate to riparian condition including both streambank erosion hazard ratings and the vegetation influence rating. This disturbance index is an overall rating that combines the streambank erosion hazard rating with the average vegetation influence rating; it is derived using the BANK and BEG fields calculated as: (BANK + VEG)/2. Where BANK is the average streambank erosion hazard rating, which contains the average streambank erosion hazard rating for each hydrologic unit (4th- or 6th-field). The hazard rating is for the dominant stream channel types in an area, using the stability ratings described by Rosgen (1994). And where VEG is the average vegetation influence rating, which contains the average vegetation influence rating for the dominant stream channel types in each hydrologic unit (4th- or 6th-field), using the stability ratings described by Rosgen (1994).

And where RECOVERY is the average recovery potential rating, which is a field that contains the average stream channel recovery potential rating for the dominant stream channel types in each hydrologic unit (4th- or 6th-field), using the recovery ratings described by Rosgen (1994). The formula uses (100 - RIP_DIST) to make the numerical expression of integrity consistent; hence a "high" recovery potential value would not cancel out a "high" riparian area disturbance index value.

Important Notes

Cumulative frequencies, expressed as percentiles, were calculated using the standard statistical formula and definition.

Field codes prefixed with an * are only in the table for 6th code watersheds H6INTERP.

Field codes prefixed with two ** are only in the table for 4th code watersheds H4INTERP.

If TEMP_ZONE = X, the HUC is outside the boundary of this coverage, which only covers the Columbia River Basin.

Some HUCs will have zero sediment values (STE, SED, BASESED, etc.). These values are zero due to missing stream coverage for these HUCs. Some HUCs will not have hazard ratings because there is missing data for some subsection/slope phase combinations. There are a few missing values for AUG_TEMP.

Common and scientific names of species.

Common name	Scientific name
Flora:	
African rue	*Peganum harmala*
Alder	*Alnus Hill*
Bitter brush	*Purshia tridentata* (Pursh) DC.
Blue-leaved penstemon	*Penstemon glaucinus*
Broad-fruit mariposa	*Calochortus nitidus*
Brome-grass	*Bromus* L.
Buck rush	*Ceanothus cuneatus* (Hook.) T. & G.
Canada thistle	*Cirsium arvense*
Cheatgrass	*Bromus tectorum* L.
Clustered lady's-slipper	*Cypripedium fasciculatum*
Common crupina	*Crupina vulgaris*
Crenulate grape-fern	*Botrychium crenulatum*
Crested wheatgrass	*Agropyron cristatum* (L.) Gaertn.
Cronquist's stickseed	*Hackelia cronquistii*
Dalmatian toadflax	*Linaria dalmatica*
Diffuse knapweed	*Centaurea diffusa*
Douglas-fir	*Pseudotsuga menziesii* (Mirbel) Franco.
Dyers woad	*Isatis tinctoria*
Grand fir	*Abies grandis* (Dougl.) Forbes
Green-tinged paintbrush	*Castilleja chlorotica*
Halogeton	*Halogeton glomeratus*
Howellia	*Howellia aquatilis*
Howell's gumweed	*Grindelia howellii*
Huckleberries	*Vaccinium* L.
Iberian starthistle	*Centaurea iberica*
Idaho fescue	*Festuca idahoensis* Elmer
Juniper	*Juniperus* L.
Kentucky bluegrass	*Poa pratensis* L.
Knapweed	*Centaurea* L.
Leafy spurge	*Euphorbia esual* L.
Lemhi penstemon	*Penstemon lemhiensis*
Lodgepole pine	*Pinus contorta* Dougl.
Long-bearded mariposa-lily	*Calochortus longebarbatus* var. *Longebarbatus*
Macfarlane's four-o'clock	*Mirabilis macfarlanei*
Malheur wire-lettuce	*Stephanomeria malheurensis*

Common name	Scientific name
Manzanita	*Arctostaphylos* Adans.
Matgrass	*Nardus stricta*
Mediterranean sage	*Salvia aethiopis*
Medusahead	*Taeniatherum caput-medusae*
Mountain hemlock	*Tsuga mertensiana* (Bong.) Carr.
Mt. Mazama collomia	*Collomia mazama*
Mulford's milk-vetch	*Astragalus mulfordiae*
Musk thistle	*Carduus nutans*
Orange hawkweed	*Hieracium aurantiacum*
Osgoodmountains milkvetch	*Astragalus yoder-williamsii*
Palouse goldenweed	*Haplopappus liatriformis*
Payson's milkvetch	*Astragalus paysonii*
Peck's mariposa-lily	*Calochortus longebarbatus* var. *Peckii*
Perennial pepperweed	*Lepidium latifolium*
Picabo milkvetch	*Astragalus oniciformis*
Ponderosa pine	*Pinus ponderosa* Dougl.
Purple loosestrife	*Lythrum salicaria*
Purple starthistle	*Centaurea calcitrapa*
Pygmy monkeyflower	*Mimulus pygmaeus*
Rush skeletonweed	*Chondrilla juncea*
Russian knapweed	*Centaurea repens*
Sagebrush	*Artemisia* L.
Saltcedar	*Tamarix ramosissima*
Scotch thistle	*Onopordum acanthium*
Spalding's campion	*Silene spaldingii*
Spiny cocklebur	*Xanthium spinosum*
Spotted knapweed	*Centaurea maculosa*
Squarrose knapweed	*Centaurea virgata*
St. Johnswort	*Hypericum perforatum*
Subalpine fir	*Abies lasiocarpa* (Hook.) Nutt.
Suksdorf's lomatium	*Lomatium suksdorfii*
Sulfur cinquefoil	*Potentilla recta*
Syrian bean-caper	*Zygophyllum fabago*
Tansy ragwort	*Senecio jacobaea*
Thompson's clover	*Trifolium thompsonii*
Twin-spike moonwort	*Botrychium paradoxum*
Upward-lobed moonwort	*Botrychium ascendens*
Washington monkeyflower	*Mimulus washingtonensis* var. *Washingtonensis*
Washington polemonium	*Polemonium pectinatum*
Weak milk-vetch	*Astragalus solitarius*

Common name	Scientific name
Western hemlock	*Tsuga heterophylla* (Raf.) Sarg.
Western juniper	*Juniperous occidentalis* Hook.
Western redcedar	*Thuja plicata* Donn.
Western white pine	*Pinus monticola* Dougl.
Wheat	*Triticum aestivum* L.
White bark pine	*Pinus albicaulis* Engelm.
White fir	*Abies concolor* (Gord. & Glend.) Lindl.
Whitetop	*Cardaria* spp.
Willow	*Salix* L.
Yellow hawkweed	*Hieracium pratense*
Yellow starthistle	*Centaurea solstitialis*
Annual, Biennial Forb:	
	Alyssum desertorum
	Amisimkia intermedia
	Blepharipappus scaber
	Clarkia pulchella
	Coldenia grandiflora
	Collinsia parviflora
	Collomia grandiflora
	Cordylanthus ramosus
	Cryptantha affinis
	Cryptantha ambigua
	Descurainia pinnata
	Descurainia richardsonii
	Draba verna
	Epilobium minutum
	Epilobium paniculatum
	Eriogonum vimineum
	Erodium cicutarium
	Euphorbia spp.
	Galium bifolium
	Gayophytum humile
	Gapophytum nuttallii
	Hemizonia pungens
	Holosteum umbellatum
	Lactuca ludoviciana
	Lagophylla ramosissima
	Layia galndulosa
	Lepidium perfoliatum

Common name	Scientific name
	Linanthus harknessi
	Lupinus microcarpus
	Madia gracilis
	madia sativa
	Microsteris gracilis
	Mimulus breweri
	Montia perfoliata
	Navarretia sp.
	Orthocarpus tenuifolius
	Phacelia linearis
	Plectritis macrocera
	Polemonium micranthum
	Polygonum majus
	Ranunculus testiculatus
	Ranunculus occidentalis
	Sanguisorba minor
	Sisymbrium altissimum
	Taraxacum ceratophorum
	Tragopogon dubius
	Verbascum thapsus
Annual Grass:	
	Agrostis interrupta
	Bromus brizaeformis
	Bromus japonicus
	Bromus mollis
	Bromus tectorum
	Festuca bromoides
	Festuca microstachys
	Festuca octoflora
	Taeniatherum asperum
Perennial Forb:	
	Achillea millefolium
	Agoseris glauca
	Agoseris grandiflora
	Allium acuminatum
	Allium douglasii
	Antennaria rosea
	Antennaria dimorpha
	Arabis hoboelii

Common name	Scientific name
	Arabis puberula
	Arabis sparsiflora
	Aster campestris
	Astragalus beckwithii
	Astragalus curvicarpus
	Astragalus filipes
	Astragalus lentiginosus
	Astragalus prushii
	Astragalus reventus
	Astragalus stenophyllus
	Balsamorhiza careyana
	Balsamorhiza sagittata
	Calochortus macrocarpus
	Castilleja applegatei
	Castilleja chromosa
	Chaenactis douglasii
	Cheilanthes gracillima
	Cirsium arvense
	Crepis acuminata
	Crepis intermedia
	Erigeron bloomeri
	Erigeron elegantulus
	Erigeron filifolius
	Erigeron linearis
	Erigeron poliospermus
	Erigeron pumilus
	Eriogonum heracleoides
	Eriogonum microthecum
	Eriogonum niveum
	Eriogonum ovalifolium
	Eriogonum sphaerocephalum
	Eriogonum strictum
	Eriogonum thymoides
	Eriogonum umbellatum
	Eriophyllum lanatum
	Fritillaria pudica
	Geum campanulatum
	Hydrophyllum capitatum
	Leptodactylon pungens
	Linum perenne

Common name	Scientific name
	Lithophragma bulbifera
	Lomatium canbyi
	Lomatium cous
	Lomatium macrocarpum
	Lomatium triternatum
	Lupinus caudatus
	Lupinus laxiflorus
	Lupinus lepidus
	Mertensia longiflora
	Microseris nutans
	Microseris troximoides
	Orobanche uniflora
	Penstemon humilis
	Penstemon gracilis
	Penstemon laetus
	Penstemon richardsoni
	Penstemon speciosus
	Petalostemon ornatum
	Phacelia hastata
	Phlox douglasii
	Phlox hoodii
	Phlox longifolia
	Potentilla glandulosa var. *intermidia*
	Ranunculus occidentalis
	Senecio canus
	Senecio integerrimus
	Sisyrinchium douglasi
	Sisyrinchium idahoense
	Stellaria americana
	Stellaria nitens
	Trifolium dubium
	Trifolium macrocephalum
	Trifolium microcephalum
	Zygadenus paniculatus
Perennial Grass:	
	Agropyron saxocpla
	Agropyron smithii
	Agropyron spicatum
	Bromus carinatus

Common name	Scientific name
	Danthonia unispicata
	Elymus cinereus
	Festuca idahoensis
	Keoleria cristata
	Oryzopsis humenoides
	Poa ampla
	Poa bulbosa
	Poa compressa
	Poa cusickii
	Poa pratensis
	Poa sandbergii
	Sitanion hystrix
	Stipa columbiana
	Stipa comata
	Stipa occidentalis
	Stipa thurberiana
Sedge:	
	Carex rossii
	Carex geyeri
	Kobresia simpliciuscula
Shrub:	
	Artemisia arbuscula
	Atremisia tridentata spp. *tridentata*
	Atremisia tridentata ssp. *wyomingensis*
	Artemisia tridentata ssp. *vaseyana*
	Artemisia rigida
	Cercocarpus ledifolius
	Chrysothamnus nauseosus
	Chrysothamnus viscidiflorus
	Grayia spinosa
	Holodiscus dumosus
	Purshia tridentata
	Ribes cereum
	Symphoricarpos oreophilus
	Tetradymia canescens
	Tetradymia glabrata

	Common name	Scientific name
Fish:		
	Bass	*Micropterus* spp.
	Bull trout	*Salvelinus confluentus*
	Brook trout	*Salvelinus fontinalis*
	Chinook salmon	*Oncorhynchus tshawytscha*
	Goose Lake sucker	*Catostomus occidentalis lacusanserinus*
	Klamath Largescale sucker	*Catostomus snyderi*
	Lahontan Cutthroat trout	*Oncorhynchus clarki henshawi*
	Lost River sucker	*Deltistes luxatus*
	Malheur sculpin	*Cottus bairdi* ssp.
	Margined sculpin	*Cottus marginatus*
	Pacific lamprey	*Lampetra tridentata*
	Pit-Klanath Brook lamprey	*Lampetra lethophaga*
	Pygmy whitefish	*Prosopium coulteri*
	Rainbow trout	*Oncorhynchus mykiss*
	Redband trout	*Oncorhynchus mykiss* ssp.
	Shorthead sculpin	*Cottus confusus*
	Shortnose sucker	*Chasmistes brevirostris*
	Slender sculpin	*Cottus tenuis*
	Sockeye salmon	*Oncorhynchus nerka*
	Steelhead	*Oncorhynchus mykiss mykiss*
	Torrent sculpin	*Cottus rhotheus*
	Walleye	*Stizostedion vitreum vitreum*
	Westslope cutthroat trout	*Oncorhynchus clarki lewisi*
	Wood River Bridgelip sucker	*Catostomus columbianus hubbsi*
	Wood River sculpin	*Cottus leiopomus*
	Yellowstone cutthroat trout	*Oncorhynchus clarki bouvieri*
Birds:		
	American kestrel	*Falco sparverius*
	American robin	*Turdus migratorius*
	Ash-throated flycatcher	*Myiarchus cinerascens*
	Bald eagle	*Haliaeetus leucocephalus*
	Band-tailed pigeon	*Columba fasciata*
	Bank swallow	*Riparia riparia*
	Barn swallow	*Hirundo rustica*
	Barred owl	*Strix varia*
	Black-backed woodpecker	*Picoides arcticus*
	Black-billed magpie	*Pica pica*
	Black-capped rosy finch	*Leucosticte arctoa*

Common name	Scientific name
Black-chinned hummingbird	*Archilochus alexandri*
Black-throated gray warbler	*Dendroica nigrescens*
Blue grouse	*Dendragapus obscurus*
Bobolink	*Dolichonyx oryzivorus*
Bohemian Waxwing	*Bombycilla garrulus*
Boreal owl	*Aegolius funereus*
Brewer's blackbird	*Euphagus cyanocephalus*
Brewer's sparrow	*Spizella breweri*
Broad-tailed hummingbird	*Selasphorus platycercus*
Burrowing owl	*Athene cunicularia*
Bushtit	*Psaltriparus minimus*

Quigley, Thomas M.; Arbelbide, Sylvia J., tech. eds. 1997. An assessment of ecosystem components in the interior Columbia basin and portions of the Klamath and Great Basins. Gen. Tech. Rep. PNW-GTR-405. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 4 vol. (Quigley, Thomas M., tech. ed.; The Interior Columbia Basin Ecosystem Management Project: Scientific Assessment).

This paper provides detailed information about current conditions and trends for the biophysical and social systems within the basin. Social and economic conditions within the assessment area differ considerably depending to a great extent on population, diversity of employment opportunities, and changing demographics. This information can be used by land managers to develop broad management goals and priorities and provides the context for decisions specific to smaller geographic areas.

Keywords: Columbia basin, biophysical systems, social systems, ecosystem.

The **Forest Service** of the U.S. Department of Agriculture is dedicated to the principle of multiple use management of the Nation's forest resources for sustained yields of wood, water, forage, wildlife, and recreation. Through forestry research, cooperation with the States and private forest owners, and management of the National Forests and National Grasslands, it strives—as directed by Congress—to provide increasingly greater service to a growing Nation.

The United States Department of Agriculture (USDA) prohibits discrimination in its programs on the basis of race, color, national origin, sex, religion, age, disability, political beliefs, and marital or familial status. (Not all prohibited bases apply to all programs.) Persons with disabilities who require alternative means of communication of program information (Braille, large print, audiotape, etc.) should contact the USDA's TARGET Center at (202) 720-2600 (voice and TDD).

To file a complaint, write the Secretary of Agriculture, U.S. Department of Agriculture, Washington, DC 20250, or call (800) 245-6340 (voice), or (202) 720-1127 (TDD). USDA is an equal employment opportunity employer.

Abstract

Quigley, Thomas M.; Arbelbide, Sylvia J., tech. eds. 1997. An assessment of ecosystem components in the interior Columbia basin and portions of the Klamath and Great Basins: volume 2. Gen. Tech. Rep. PNW-GTR-405. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 4 vol. (Quigley, Thomas M., tech. ed.; The Interior Columbia Basin Ecosystem Management Project: Scientific Assessment).

The *Assessment of Ecosystem Components in the Interior Columbia Basin and Portions of the Klamath and Great Basins* provides detailed information about current conditions and trends for the biophysical and social systems within the Basin. This information can be used by land managers to develop broad land management goals and priorities and provides the context for decisions specific to smaller geographic areas. The Assessment area covers about 8 percent of the U.S. land area, 24 percent of the Nation's National Forest System lands, 10 percent of the Nation's BLM-administered lands, and contains about 1.2 percent of the Nation's population. This results in a population density that is less than one-sixth of the U.S. average. The area has experienced recent, rapid population growth and generally has a robust, diverse economy. As compared to historic conditions, the terrestrial, aquatic, forest, and rangeland systems have undergone dramatic changes. Forested landscapes are more susceptible to fire, insect, and disease than under historic conditions. Rangelands are highly susceptible to noxious weed invasion. The disturbance regimes that operate on forest and rangeland have changed substantially, with lethal fires dominating many areas where non-lethal fires were the norm historically. Terrestrial habitats that have experienced the greatest decline include the native grassland, native shrubland, and old forest structures. There are areas within the Assessment area that have higher diversity than others. Aquatic systems are now more fragmented and isolated than historically and the introduction of non-native fish species has complicated current status of native fishes. Core habitat and population centers do remain as building blocks for restoration. Social and economic conditions within the Assessment area vary considerably, depending to a great extent on population, diversity of employment opportunities, and changing demographics. Those counties with the higher population densities and greater diversity of employment opportunities are generally more resilient to economic downturns. This Assessment provides a rich information base, including over 170 mapped themes with associated models and databases, from which future decisions can benefit.

Keywords: Columbia basin, biophysical systems, social systems, ecosystem.

INTRODUCTION

Landscape ecology was defined by Forman and Godron (1986) as the study of the structure, function, and change in a heterogeneous land area comprising interacting ecosystems. In North America, the science of landscape ecology has developed rapidly since the 1970s. The recent proliferation of landscape ecology literature and its associated application in resource management and land-use planning has been fueled in part by the complexity of multi-scale issues related to achieving public objectives for sustaining resource production and the biological diversity (or biodiversity) of native[1] systems. These issues have required the rapid implementation of relatively new and non-traditional ecosystem management principles, assessment techniques, and management prescriptions at landscape levels, in both public and private natural resource management (Bourgeron and others 1994, Box 1995, Everett and others 1994a, Haynes and others 1996, Jaindl and others 1996, Jensen and Everett 1994, Kennedy and Quigley 1994, National Research Council 1994, Quigley and others 1996).

A pervasive polarization of society has developed concerning land management that allows resource production while conserving biodiversity. Many of these polarized views are not supported by scientific foundation, but reside in the beliefs and values of people. Traditional commodity practices that mitigate for ecological concerns have generally not sustained either native biodiversity or the productive capacity of commodities. Consequently, many people who place a high value on the sustainability of biodiversity believe that relatively large proportions of wildlands should be managed as reserves, in which the influences of human activities are minimized. These differing viewpoints reflect natural resource management techniques that developed in North America, although they were based on European land-management philosophies.

Traditional commodity, reserve, and multiple-use management originated in Europe at a time when much of the landscape had already been substantially altered and was generally dominated by species that had adapted to human disturbances. Consequently, when these concepts were applied to North America, which had a very different environment and complex of species, there were concurrent deleterious effects on land capability and native biodiversity. An historical account of how the philosophies of resource development affected forest, rangeland, and fire in North America was thoroughly discussed by Langston (1995), Manning (1995), and Pyne (1995). The implications and forecast of the potential outcomes of this European-based approach to land

[1] As defined in this chapter, native means plants or animals that are indigenous to a given place; growing, living, or produced originally in a given place. More specifically, when native is used to describe a system or regime, we are specifically referring to the "pre-Euro-American settlement" system which is synonymous with the historical range of variability (HRV) regime. Our historical data refers to information recorded during the early decades of Euro-American settlement of the Basin (circa 1850s).

management, as well as the argument for an ecological management alternative, were discussed in a philosophical context in the 1860s by Marsh (1907) and in the 1940s by Leopold (1949).

Information has increased concerning emerging problems relative to forest and rangeland health and the need for consideration of ecological structure, function, and process (Covington and others 1994, DellaSala and others 1995, Everett and others 1994b, Jaindl and Quigley 1996, Kolb and others 1994, Mutch and others 1993, National Research Council 1994, Sampson and Adams 1994). Many articles are available concerning the assessment and analysis of ecological conditions (Diaz and Apostol 1992, Hessburg 1993, Jensen and Bourgeron 1994, Morelan and others 1994, Shlisky 1994, U.S. Department of Agriculture 1992).

In the western United States, the application of traditional land-management philosophy appears to have been detrimental to long-term sustainability as evidenced by the reduction of native biodiversity, accelerated rates of soil erosion, and an increasing trend in area burned by wildfire (Ehrlich 1988, Harvey and others 1994a, Johnson and others 1994, Megahan 1991, Raup 1988, Wilson 1988). In general, prior to human-caused disturbances, major changes in native biodiversity were a result of substantial shifts in climate or geology. However, human influences have substantially affected ecological processes and biodiversity, and they will likely continue to do so in the future.

Agee (1993) displayed the areal extent of wildfires in Pacific Northwest forests from 1916 through 1992. He concluded that the recent increasing trend of forests disturbed by wildfires was correlated to the advancement of fire suppression technology and fuel accumulations. For example, in the early 1900s, fire intervals were generally synchronized with fuel accumulations. With the advent of improved technology for fire detection, prevention, and suppression in the 1930s, the areal extent of wildfires generally declined through the 1960s. However, with steadily increasing fuel accumulations, number of ignitions, and fire size and intensity, wildfires have overcome the human energy available for fire suppression. The area burned by wildfires steadily increased between the 1970s and 1990s, and at present, is approaching or exceeding levels experienced in the early 1900s, when fire suppression resources were relatively low.

The effects of excessive livestock grazing pressure were evident on rangelands as early as the 1890s (Griffiths 1902). Forage consumption by livestock had altered fire regimes. Livestock had also impacted hydrologic systems by increasing soil erosion, increasing sediment delivery to streams, and affecting the function of riparian communities.

This chapter addresses the following questions concerning the ecological state of landscapes within the Basin:[2]

- What are the status and trends of landscape processes and functions within the Basin? What are the causal agents responsible for the detected trends?
- How will current and future landscape disturbance regimes affect landscape patterns and biophysical potentials? What are the probable trends of disturbance regimes in response to various landscape management futures?
- What are the historical[3] and probable future trends of landscape elements important to commodity and amenity resource flows under various landscape management strategies?
- What are the probable trends of biophysical functions and processes for various landscape

[2] The Basin is defined as those portions of the Columbia River basin inside the United States east of the crest of the Cascades and those portions of the Klamath River basin and the Great Basin in Oregon.

[3] As defined in this chapter, historical refers to the "post-Euro-American settlement" time period; early historical refers specifically to the 1800s, while recent historical refers to the 1900s. This is not synonymous with historical range of variability (HRV) which refers to the "pre-Euro-American settlement" or "native" regime (see footnote 1).

management futures? What will be the opportunities, tradeoffs, and consequences of various landscape management futures for long-term productivity, nutrient and carbon cycling, and biogeochemical processes?

The objective of the landscape assessment is to display an understanding of the spatial and temporal dynamics of landscape patterns, and their relation to social, economic, terrestrial, and aquatic systems. In order to assess biodiversity, ecological integrity was evaluated. That is, we assessed the ability of landscapes to renew themselves while taking into account their paleoecological, historical, current, and future biophysical potentials. This assessment of the Basin was based on the principles and methods outlined by Allen and Hoekstra (1992), Forman (1995), Forman and Godron (1986), King (1990), and Turner and Gardner (1990). Many of the methods published by Hessburg (1993), Jensen and Bourgeron (1994), Keane (1987), and Keane and others (1989, 1990a, 1990b, 1990c) were also incorporated. In addition, many methods were created through an iterative process as the assessment was conducted (see Keane and others 1996a).

Key Ecosystem Processes and Functions

Key ecosystem processes are those that control or limit the potentials for biotic productivity, resilience to disturbance, and biological diversity. These processes are studied by ecosystem ecologists in the guise of the circulation, transformation, and accumulation of energy and matter through the biotic and abiotic systems (Cockburn 1991, Ulanowicz 1992, Waring and Schlesinger 1985). Flows in matter such as carbon and nutrients, organisms, populations, communities, and ecosystems are driven by the input of solar energy. All ecosystem processes are spatially and temporally dynamic, equating to the flows of energy, matter, genetic information, communities, and populations. The key processes developed through geologic and evolutionary time at relatively specific landscape scales (fig. 3.1).

The key processes that we focused our attention on included (1) energy flows, (2) the hydrologic cycle, (3) the carbon and nutrient cycles, (4) ecosystem food webs, and (5) evolution (Allen and Hoekstra 1992, Barbour and others 1980, Brown and Gibson 1983, Cockburn 1991, Ehrlich 1986, Forman and Godron 1986, Jenny 1980, Kimmins 1987, Naveh and Lieberman 1994, Running 1990, Thornbury 1969, Trewartha and Horn 1980, Waring and Schlesinger 1985). The evolutionary status of organisms constrains the development of biophysical conditions (Cockburn 1991, Jenny 1980, Ulanowicz 1992). In turn, biophysical conditions constrain evolutionary processes. Consequently, key ecological processes and functions are tightly woven and interdependent, and their changes accrue slowly but predictably. In contrast, when humans disrupt the interrelationships, change may occur rapidly or in opposition to ecological cause-and-effect relationships. In response, the systems become largely unpredictable.

The following discussion provides a description of these key processes as they developed through geologic and evolutionary time without substantial influence from humans, that is, without human intervention which alters ecological cause and effect, or changes the scales of effects. Understanding the development of the key processes in this manner provides the context necessary for understanding the mechanisms responsible for observed or predicted relationships between the biological and physical components of landscapes.

Although energy flows operate at virtually every scale, they are best quantified at the global scale. Energy inputs are driven by the relationship between solar radiation and the biosphere, and then distributed across continents and oceans (fig. 3.1). All ecological processes are driven by energy flows. For example, the distribution of energy is reflected in climatic variables including precipitation, temperature, and wind. These variables in turn regulate the hydrologic and carbon-nutrient cycles, which subsequently affect ecosystem food webs. Food webs are spatially and temporally explicit networks of producers, consumers, and

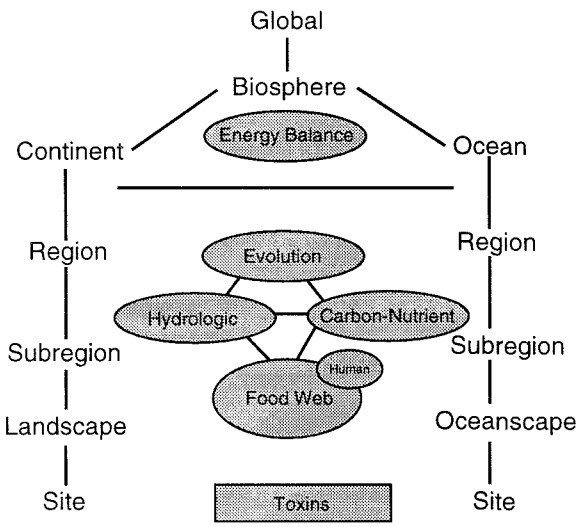

Figure 3.1—Pre-historical (native or HRV) relationships of key processes at different scales.

decomposers linked by trophic interactions and disturbance processes (Allen and Hoekstra 1992; Ulanowicz 1992). Fire, a secondary energy process, is strongly correlated with the carbon-nutrient cycles and the hydrologic cycle. Fire frequency, extent, and severity are controlled to a large degree by the availability of carbon, as well as the moisture regime. Energy flows are also influenced by geologic (volcanics, plate tectonics, and meteor impacts), geomorphologic (landform development), climatic (global temperature change), and anthropogenic processes (combustion of fossil fuels).

Although the hydrologic cycle operates within the entire global system, the variability of hydrologic systems can be effectively stratified at the subregional scale (fig. 3.1). The hydrologic cycle involves the movement of water and its associated energy, nutrients, and other matter through the biosphere, hydrosphere (ocean circulation), and cryosphere (snow and ice cover). In simplistic terms, water evaporates from aquatic environments (predominantly the oceans), precipitates onto terrestrial environments, enters fluvial systems through surface and subsurface flows, then returns to the oceans via stream discharge. Again, solar radiation drives the hydrologic cycle. The hydrologic cycle functions as a direct linkage between terrestrial and aquatic systems. On land this involves a cycle of precipitation, transpiration from floral communities, evaporation, and water flow over or through the soil to rivers and streams. In oceans this involves a cycle of precipitation, water flow from rivers and streams, and evaporation. Rivers and streams provide direct connections from the land to the ocean. River and stream flows are generally limited by precipitation and transpiration. Erosion and material transport are controlled by climate, weather, vegetation cover, topography, parent material, soil structure, and disturbance events.

Riparian systems (that is, areas adjacent to water) strongly affect the cycle of water by ameliorating water temperature and providing storage. These systems fill with water during spring snowmelt and from spring, summer, or fall rain storms, thus influencing runoff and flood events. Water stored in riparian soils is slowly released into streams and lakes during the summer drought season, thus supplementing stream flow, photosynthesis, and transpiration throughout the summer and fall. Groundwater from upland sites can also supplement flows into springs and streams during droughts.

Carbon and nutrients also cycle through the biosphere, but because these cycles are closely associated with the hydrologic cycle, their variability can also be effectively stratified at subregional scales (fig. 3.1). Dominant processes of the carbon-nutrient cycles include photosynthesis and nutrient uptake by producers, respiration by consumers, and decomposition by decomposers. Fire is also an important process that hastens the release of carbon and nutrients from plants into the soil and atmosphere. Photosynthesis, the process in which carbon is fixed from carbon dioxide in the atmosphere, is controlled by solar radiation, temperature, precipitation, and evolutionary adaptations of green plants. Productivity of the biotic communities is directly influenced by

carbon-nutrient cycles. In turn, the recovery from or resilience of communities to disturbance is largely a result of site productivity, as well as evolutionary adaptations of the biotic community to disturbance processes and patterns. Decomposition rates are controlled by temperature and precipitation; rates are faster in warm and moist environments than in cold and dry environments.

Fire and herbivory disturbance processes are indirectly linked to the carbon-nutrient cycle. More productive environments have more biomass available as fuel for fires and as food for herbivores. Nutritious foods are also commonly more available on productive sites. In addition, in that nutritious plants also tend to be palatable, they commonly attract the attention of herbivores. Evolutionary processes promote plants that conserve nutrients in nutrient-limited systems.

In simplistic terms, ecosystem food webs indicate the relationships among food production, consumption, and decomposition (Allen and Hoekstra 1992), and demonstrate the relationship between species and ecosystems. Although ultimately controlled by energy flows, food webs are more directly influenced by climate, and the hydrologic and carbon-nutrient cycles. Ecosystem food webs developed as a result of co-evolution processes among the biota of an explicit and relatively small geographic area. The variability among ecosystem food webs is effectively stratified at the subregional scale (fig. 3.1). Humans evolved within these food webs, their associated energy flows, and ecosystem cycles (Fagan 1989). Predator-prey relationships (including plant-herbivore associations) developed as a result of evolutionary processes that selected against genotypes and phenotypes that were less fit for particular environmental conditions (including disturbance processes). The responses of predator-prey relationships are highly variable because of prey response to disturbance, environment, disease, and predation, and predator response to the prey base, disturbance, and environment.

In its broadest context, evolutionary processes involve the origin and maintenance of biological diversity, both within lineages (that is, adaptation by natural selection and genetic drift), and among lineages (that is, speciation, extinction, and biogeographic colonization)(Cockburn 1991; Ulanowicz 1992). Thus, evolution involves the cumulative change in the characteristics and genetic information of organisms, populations, and species. Because evolutionary dynamics are constrained by ecosystem processes, evolutionary processes are highly correlated with the biophysical environment, including disturbance regimes and competitive strategies at the regional and subregional scales (fig. 3.1). The loss of genetic information and extinction of species usually occurs as a result of climatic changes or altered disturbance regimes and their collective effects on suitable habitats, or by a change in competition within or between species. The primeval extinction of species typically occurred as a result of infrequent, catastrophic volcanic and solar events, or due to the cumulative change in bioedaphic and climatic conditions that occurred at a rate faster than a species could adapt.

Adaptation is a process of evolutionary modification over long time periods that results in improved survival and reproductive efficiency. These adaptations occur across the full range of specialist and generalist species that are best suited to an environment and its disturbance regimes. Populations and species are typically capable of migrating within a particular set of life zones at a regional scale, in response to weather fluctuations, changing climate, loss of habitat, and catastrophic geomorphologic events.

Landscapes develop and change through geologic and evolutionary time. The climate changes largely as a result of solar cycles and conditions of the biosphere, particularly the hydrosphere (ocean circulation) and cryosphere (snow and ice cover). Biosphere conditions can either (1) increase global absorption of solar energy due to an increase of atmospheric carbon dioxide, or (2) increase global albedo (reflectivity) due to deforestation, agricultural development, and/or excessive grazing

(Kimmins 1987, Waring and Schlesinger 1985). Hydrologic systems may change as a result of climatic, geomorphologic, biotic, and edaphic processes. Landforms change over time in response to geomorphologic processes that are controlled by the hydrologic system, climate, and geologic conditions. Soils change over time in response to fluctuations of climatic, geomorphologic, hydrologic, and biotic processes. Biotic communities, and subsequently ecosystem food webs can change as a result of any, or all, of the above-mentioned changes. Landscapes and regions change over time in response to the combined and interacting fluctuations of energy flows, biotic communities, and climatic, geomorphologic, and hydrologic processes.

Classifying ecological systems in ways that integrate the key ecosystem processes could facilitate an understanding of the mechanisms behind dynamic landscapes. For example, with respect to biotic communities, a classification involving potential vegetation types or indicator species could express aquatic, riparian, or terrestrial upland capabilities. In addition, a landform or soil classification system that is correlated with potential vegetation types, and a hydrologic classification system that is correlated with potential aquatic communities could help to integrate the primary ecosystem processes and predict responses to varying disturbance regimes.

Ecological Equilibrium in the Native System

In the native system, the key ecosystem processes discussed in the foregoing section were in dynamic equilibrium. We do not consider conditions of ecological equilibrium to be static or stable, but rather to maintain similar relationships between inputs and outputs of biotic and abiotic energy and materials. These relationships conserved energy and generally maintained carbon, nutrients, water, and subsequently foods (for producers, consumers, and decomposers) within their ecological scales of spatial and temporal change. Furthermore, genetic information, and consequently, biological diversity were also conserved.

A system in ecological equilibrium has cyclic successional patterns or multiple stable states, and associated responses to disturbance (Allen and Hoekstra 1992, Naveh and Lieberman 1994, Rosgen 1996, Tausch and others 1993). As shown in figure 3.2, native system equilibrium is analogous to a balance or scale in which the fulcrum is representative of biotic potential (terrestrial and aquatic), and the platform corresponds to geologic parent material; the parent material, in turn, is shaped by geomorphologic processes, which are overlain by soil formed through pedogenic processes. The sphere surrounding our hypothetical scale in figure 3.2 is affected by climatic processes. The carbon-nutrient and hydrologic cycles are generally in balance, due in part to mediation from the biotic community (Cockburn 1991; Ulanowicz 1992). Disturbances caused by climatic, geomorphologic, biotic, and fire processes may shift the balance point, but the response would be largely predictable. For example, if soils developed a deeper profile, their water-holding capacity would likely increase. The productivity of vegetation may subsequently increase, thereby increasing transpiration rates and decreasing soil moisture. Furthermore, using this example, fire-return intervals would probably increase, as would fire severity.

The relationships between the carbon-nutrient and hydrologic cycles and the responses to disturbance, determine the composition and structure of terrestrial and aquatic communities at any given time. In other words, states of terrestrial and aquatic communities occur as a shifting mosaic across space and through time, due to the disturbance responses and subsequent changes in their biotic and abiotic environments. Secondary disturbances (such as drought, wind, fire, floods, predation, and herbivory) cause shifts in the balance point, but again, the responses are largely predictable.

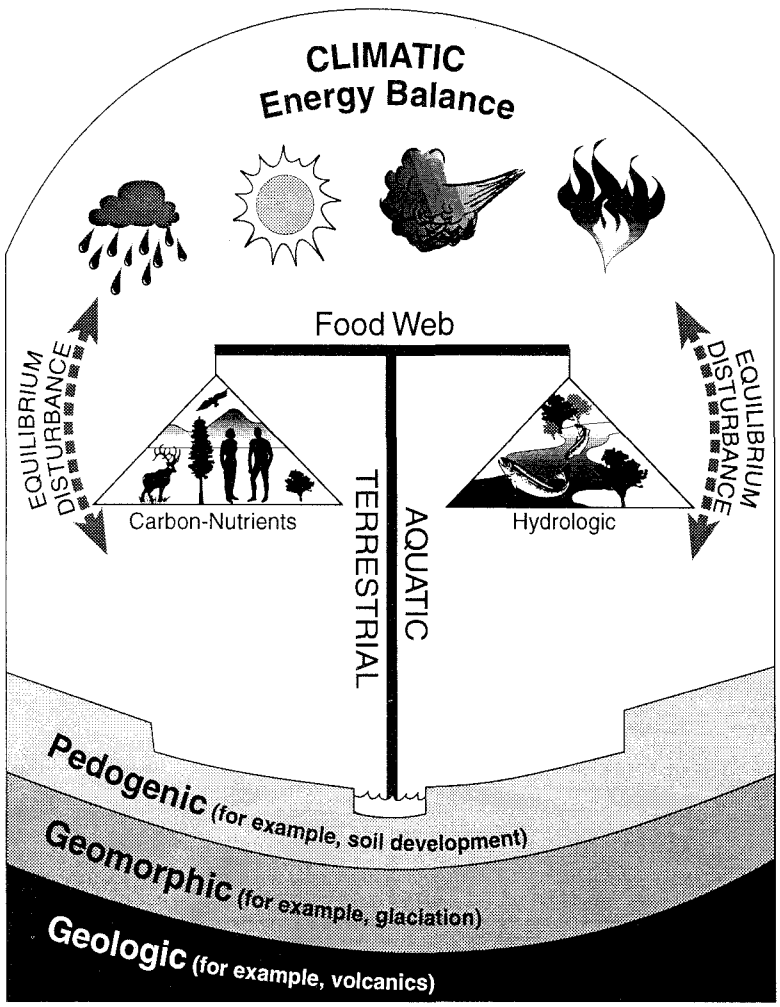

Figure 3.2—Schematic of pre-historical (native or HRV) ecological equilibrium in relation to biophysical conditions, key processes, and disturbance.

Energy, hydrologic, carbon-nutrient, and trophic systems, and subsequently evolutionary systems, cycle within explicit spatial and temporal scales. Typically, changes of the native system equilibrium were due to frequent, small magnitude fluxes of energy or material inputs and outputs that occurred throughout a long temporal period. Or, changes resulted from infrequent, large magnitude fluxes that occurred within more localized areas. Regardless of the spatial and temporal scales in which the primary processes varied, the systems remained balanced, and responses were predictable. These tightly woven processes and responses were a result of eons of evolutionary adaptations of the biotic communities, which mediated ecosystem functions (Cockburn 1991; Ulanowicz 1992). Disturbances capable of altering the relationships among the key processes typically occurred very slowly (such as climate change, glaciation, or other geomorphologic processes) which allowed for the migration and natural selection of genetic information contained within species. For example, a slow-warming climatic period would likely cause glacial recession. Flora and fauna that were adapted to cooler climates would migrate toward higher latitudes and elevations. Species adapted to warmer climates would also shift their ranges to higher latitudes and elevations. However, changes also occurred rather rapidly as a result of catastrophic geomorphological events (for example, volcanic events, meteor impacts, flooding by glacial lakes, or landslides and mudslides resulting in new landforms). Depending upon the spatial extent of these more rapid changes, some biotic entities were capable of adjusting and others were not. Catastrophic events would commonly initiate primary successional processes, and could cause a shift of the ecological equilibrium. Even so, the interrelationship of the key processes would not change substantially and the ecosystem would remain in a similar state of dynamic equilibrium.

Changes in biotic processes and potentials are strongly affected by the migration of populations and species. Migration of more competitive species into new environments occurred throughout

geologic time, but at relatively slow rates. This allowed indigenous species the opportunity to develop competitive adaptations or emigrate to new areas with less intense competition. In addition, slow migrations of species did not usually allow migrants the opportunity to isolate themselves from their parasites and pathogens. On the other hand, rapid migration across long distances (movement common to many of the species currently considered as exotic pests) may have allowed the migrants to become isolated from their controlling agents (that is, sympatric competitors, predators, parasites, and pathogens). In addition, many exotics considered pests within the New World are commonly better adapted to anthropogenic disturbances. Their competitive advantage relative to the indigenous species of the New World was a consequence of their evolution within areas under the long-term influence of human disturbances. Thus, not only are many of the New World exotics better adapted to human disturbances, but many are isolated from their natural controlling agents.

The last 1.6 million years, known as the Quaternary Period, have been dominated by continental and mountain glaciation, and cold climates with short interglacial warming periods. Catastrophic volcanic and glacial flood events were relatively common during this period. Many species that adapted to the conditions of the Quaternary Period are presently within the Basin. The migrations and evolutionary developments of biota in the Basin occurred during varying periods of climatic warming and cooling. On average, these fluctuations occurred within 8 to 10 degrees Celsius of current minimum and maximum temperatures within the Basin (fig. 3.3; Hann and others 1997, Mehringer 1996, Tausch and others 1993, Webb and Bartlein 1992). Ecosystem attributes such as biotic communities, aquatic sediments, and stream flows (fig. 3.3) responded to the climatic changes in a similar rhythm. In the northern portions of the Basin, the fluctuating climate corresponded with periods of expanding or receding continental and mountain glaciation. In the southern portions of the Basin, the extent of cold grasslands and cold forests increased during colder periods, whereas the extent of semi-desert shrublands and drier forests increased regionally during the warmer periods. During colder periods, geomorphologic processes were dominated by glacial scouring, whereas fluvial erosion and deposition were important land-forming processes during the warmer periods.

Although the climate fluctuated between colder and warmer periods, colder climates prevailed throughout most of the Quaternary Period.

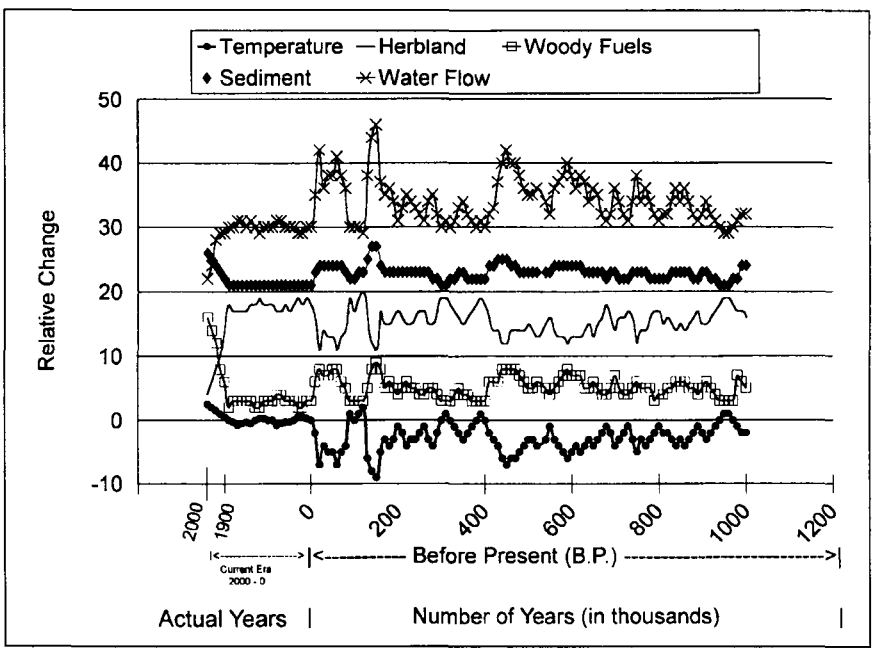

Figure 3.3—Relative changes in temperature, woody fuels, herbland, sediment, and water flow over time [adapted from Tausch and others (1993)].

Consequently, evolutionary processes (especially adaptation by natural selection) evident during the Quaternary period, were driven by cooler temperature regimes and the associated types and quantity of precipitation (Bennett 1990, Gould 1991, Tausch and others 1993). Interglacial warm periods appeared to have been too short and too divergent to substantially affect evolutionary processes. Thus, the extant genotypes in the Basin that are favored by warmer climates, likely developed during warmer temperature regimes prevalent during the Tertiary period (prior to the Quaternary period).

During the shorter interglacial warming periods, the primary strategy for species and population survival was the migration of cooler climate-adapted species and populations to northerly latitudes, higher elevations, and cooler microsites. Consequently, their ranges became more fragmented, and possibly isolated to mountaintop settings. Species and populations that had adapted to warmer conditions were capable of expanding their ranges into more northern latitudes and higher elevations. Their ranges became less fragmented. Species better adapted to fire-prone ecosystems were also able to expand their ranges and increase their population densities during the interglacial warming periods.

Extinction of species and populations adapted to cooler temperature regimes occurred during interglacial periods when migration strategies were not adequate to offset changes in interspecific competition and predation, more frequent and severe fire disturbance, loss of habitat, and stresses stemming from increased temperatures. For instance, many species of mega-fauna in the Western Hemisphere were lost by 10,000 to 4,000 years ago (Geist 1989, Gould 1991, Grayson 1993, Kurten and Anderson 1980, Lewin 1987). These extinctions appeared to have occurred in response to climatic warming and subsequent drought; reduced availability of productive cold, dry grassland communities; and possibly due to hunting by the relatively recent migrants from Asia — humans.

Human Ecological Activities

Although humans had sustained fairly wide-ranging migratory patterns over the course of their evolution, their direct and indirect influence on ecosystems processes primarily extended only to a subregional scale (fig. 3.1). Similarly, in the absence of human energy, the variability of hydrologic, carbon-nutrient, food web, and evolutionary processes could be effectively stratified at the subregional scale. Ecosystem toxins were buffered, relatively immobile, and inert during this primeval period. Regional boundaries, and to a lesser degree subregional boundaries, were relatively distinct. In particular there was a marked boundary between continental and maritime regions. Most systems conserved nutrients, food, materials, and energy within relatively closed cycles. These systems moved materials relatively slowly, and accepted and expelled energy at relatively equal rates. Events occurred that would shift equilibrium, but they were usually very infrequent and only affected sites or landscapes within a subregion.

As the global human population increased and their technologies (such as agricultural, mechanical, and chemical) developed (providing food, shelter, clothing, transportation, and recreation), the dynamic ecological equilibrium shifted to disequilibrium (fig. 3.4). As a result of these changes, human-induced processes became a significant influence on biotic and abiotic systems (Naveh and Lieberman 1994; fig. 3.5). Anthropogenic activities increased the permeability of regional and subregional boundaries. Oceans and continents were no longer effective barriers to migration and colonization. Distinct hydrologic and carbon-nutrient processes were no longer constrained mostly to subregional scales. Energy flows, hydrologic cycles, carbon-nutrient cycles, ecosystem food webs, and evolutionary processes changed to the extent that the dynamic balance, resiliency, and predictability of many systems declined. The development of human technologies also increased the mobilization and reactivity of toxins throughout the biosphere (Allen and Hoekstra 1992). As a result of these changes

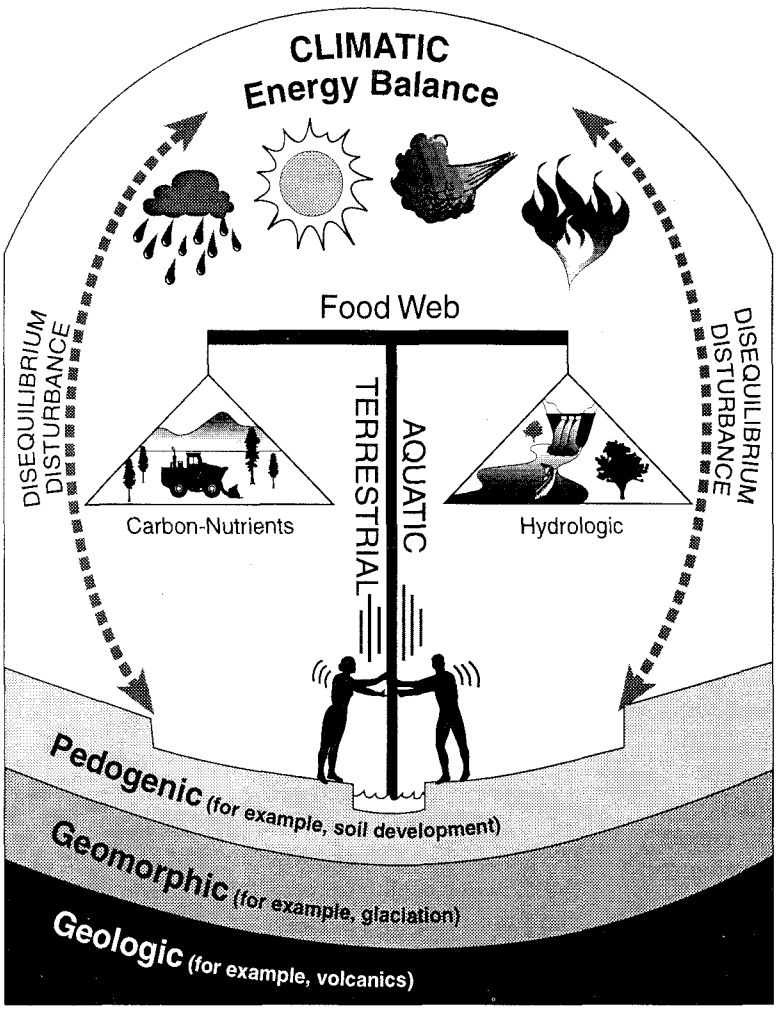

Figure 3.4—Schematic of effects of current period in relation to disequilibrium of key ecological systems.

brought about by human population growth and technological developments, long-standing ecological cause-and-effect interrelationships between different species and their environment were disrupted. Over time, species and landscape patterns that had evolved complex adaptations within well developed biophysical environments became simplified. This simplification occurred because only generalist species and poorly developed biophysical environments can be sustained in the face of chaotic cause-and-effect relationships.

Ecological Disequilibrium

Ecological disequilibrium has unequal relationships of inputs and outputs, and thus, does not have predictable cyclic successional patterns or stable states and associated responses to disturbance. Many of the relationships that are apparent during periods of ecological equilibrium are no longer apparent during periods of disequilibrium. For example, during ecological equilibrium when average temperatures are high, the relative availability of woody fuels in forest settings is low because fire frequency is relatively high. Furthermore, because fire severity would also be low, the system would be relatively resilient. After fire disturbance, vegetation would quickly return to pre-disturbance conditions, thereby recovering pre-disturbance energy flows, carbon-nutrient cycles, hydrologic cycles, and ecosystem food webs. Similarly, when average temperatures are low the availability of woody fuels in forest settings would be relatively high because of moist conditions and as a result fire frequency would be rather low. Even though fire severity would likely be high because of more fuel, the recovery rates would be relatively fast because productivity would also be high given the moister conditions. Thus, in the foregoing example, regardless of the climatic conditions, ecosystem resiliency would be high. However, these relationships are not as apparent during periods of disequilibrium. Using the above example, fire frequencies might be low even during warmer climatic regimes as a result of fire exclusion and traditional forestry and grazing practices that remove fine fuels. Recovery of vegetation to pre-disturbance conditions would be prolonged because of lower productivity in a drier regime, higher fuel loading, and increased fire severity. Consequently, the ecosystem would likely be less resilient.

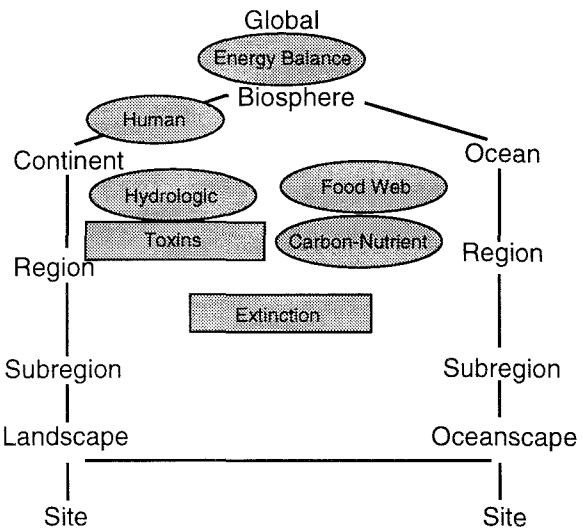

Figure 3.5—Current period relationships of key ecological systems at different scales.

Because of their aridity and certain soil properties, both of which limit plant establishment and growth, rangeland environments are extremely sensitive to stresses that disrupt their equilibrium. Inherently, many rangeland systems are less resilient than most forest systems. Consequently, recovery of rangeland vegetation to pre-disturbance conditions is inherently slow. Furthermore, the magnitude of stress necessary to shift rangeland states into disequilibrium is much smaller than that required to shift forest systems into disequilibrium. Virtually any system occurring at the extreme of its environmental gradient has high inherent natural stress and is predisposed to ecological disequilibrium.

Assessment of Key Ecosystem Processes and Functions

The following subsections on scale, biophysical template, historical range of variability (HRV),[4] succession and disturbance regimes, landscape patterns, and biogeophysical processes describe the concepts about the dominant ecological processes and functions relative to the landscape of the Basin used in our assessment.

Scale

As defined by Turner and Gardner (1990) for use in landscape ecology, scale is the spatial or temporal dimension of an object or process, characterized by both grain and extent. In landscape ecology, there are three spatial scales: region, landscape, and landscape element (Forman 1995, Forman and Godron 1986). "Regions" reflect the broadest scale (that is, have the largest geographic extent) and comprise a coarse-grained pattern of connected landscapes with contrasting boundaries that have a similar macroclimate and sphere of human activity and interest (Forman 1995). A "landscape" is a spatially heterogeneous area with repeating patterns of elements and associated disturbance regimes with similar climate and geomorphology (Forman and Godron 1986, Turner and Gardner 1990). A "landscape element" is the basic individual, population, habitat, patch, or corridor created by abiotic, biotic, or human activities. The aggregation of similar landscape elements is referred to as a "land unit." Zonneveld (1989) described land units as areas that are homogeneous relative to the scale of mapping and to the features being mapped (for example soil types, plant communities, landforms, and cover types).

The landscape assessment was considered broad in scale because it included a large regional area (Forman 1995, Turner and Gardner 1990). Continuous coarse-grained data, and mid- and fine-grained sampled data were evaluated to answer the primary questions of the assessment that involved broad-, mid-, and fine-scale landscape composition and structure. The project framework provided an overview of the uses and applications of various planning scales (Haynes and others 1996).

Our ability to address multi-scaled issues required a multi-scaled, hierarchical approach. Similarly, our ability to perceive change was dependent upon the scale of analysis. Since the issues brought forth

[4] As defined in this chapter, historical range of variability or HRV refers to the "pre-Euro-American settlement" or "native" regime. It is not synonymous with the historic or historical time period which we define as occurring in the "post-Euro-American settlement" time period.

during this assessment process were multi-scaled, the resolution of our analyses also had to vary from coarse to fine, depending on the element of concern. For example, samples at the subwatershed (6th field hydrologic unit codes or HUCs) and plot levels were used to characterize mid- and fine-scale attributes, respectively. The trends of mid- and fine-scale attributes were then statistically extrapolated and correlated with continuous broad-scale data (King 1990). The mid-scale analysis (Hessburg and others 1996a) and plot data was also used to validate and help interpret broad-scale trends of mid- and fine-scale elements. Furthermore, the mid-scale assessment considered the context of the broad-scale information as well as the trends of the fine-scale data. Our hierarchical approach provided a basis for understanding the spatial and temporal dynamics of regions, landscapes, and landscape elements.

We used three regional levels of analyses to assess ecosystem dynamics. The largest region used for the analysis was the "landscape characterization area" (LCA). The LCA was developed using Bailey's (1995) ecoregion maps to the "section" level, as refined by Nesser and Ford (1995)(map 3.1). Generally, the LCA included all sections that occurred in whole or in part within the Basin. However, the western boundary of the LCA was delineated by the watershed divide along the Cascade crest. This gave us a complete regional context for the Basin. The second level of regional analysis was the Basin (see Columbia River Basin Assessment Area on map 3.2). This area included Oregon and Washington, east of the Cascade crest, and the portions of Idaho, Montana, Wyoming, Utah, and Nevada that occurred within the Columbia River basin. These delineations were primarily oriented toward public land-management planning boundaries (see Chapter 1 of this document for further discussion). Most of the results were also summarized using the 13 Ecological Reporting Units (ERUs)(map 3.3) that were primarily aggregates of subbasins (4th field HUCs) having similar broad-scale vegetation, landform, and geomorphologic patterns. However, in some instances, the ERU delineations required splitting subbasins (that is, using subwatershed boundaries) because the subbasins contained major differences in landforms and vegetation. Due to the fact that similar types of broad-scale geographic features were found in several ERUs, the ERUs were collapsed into six areas with regional differences in landforms and climate, called "subbasin groups." At the broad scale, the subbasin groups adequately stratified the geographic differences of biophysical environments and provided a more simplified grouping system (map 3.4; table 3.1).

We used subwatersheds (6th field HUCs)(map 3.5) and subbasins (4th field HUCs)(map 3.6) as two levels of the landscape scale (see Biophysical, Chapter 2 of this document for a description of hydrologic unit codes). Subwatersheds ranged from less than 1,000 to more than 85,000 hectares and contained a repeating pattern of vegetation and similar climate, landforms, disturbance regimes, and land-use patterns. Subbasins, a coarser landscape delineation, were aggregations of subwatersheds and ranged in size from approximately 500,000 to 1,000,000 hectares. At a coarser scale, subbasins also contained a repeating pattern of vegetation and similar climate, landforms, disturbance regimes, and land-use patterns.

With respect to resolution or grain, 1-square-kilometer pixels were used to characterize landscape elements [for example, potential vegetation types (PVTs), cover types, and structural stages] for broad-scale analyses. For finer-scale information, Hessburg and others (1996a) used 4-hectare polygons to characterize mid-scale landscape patterns, and Hann and others (1997) used 375 square-meter macroplots to assess vegetation composition and structure, fuel loading, and soil cover.

Biophysical Template

In this chapter, the basis for the definition of biophysical template comes from the work of Jenny (1958) and Major (1951). They developed similar concepts of primary variables that produce the soils and vegetation of various landscapes. The biophysical template can be visualized as the

Table 3.1—Comparison of geographic area stratifications of the Basin.[1]

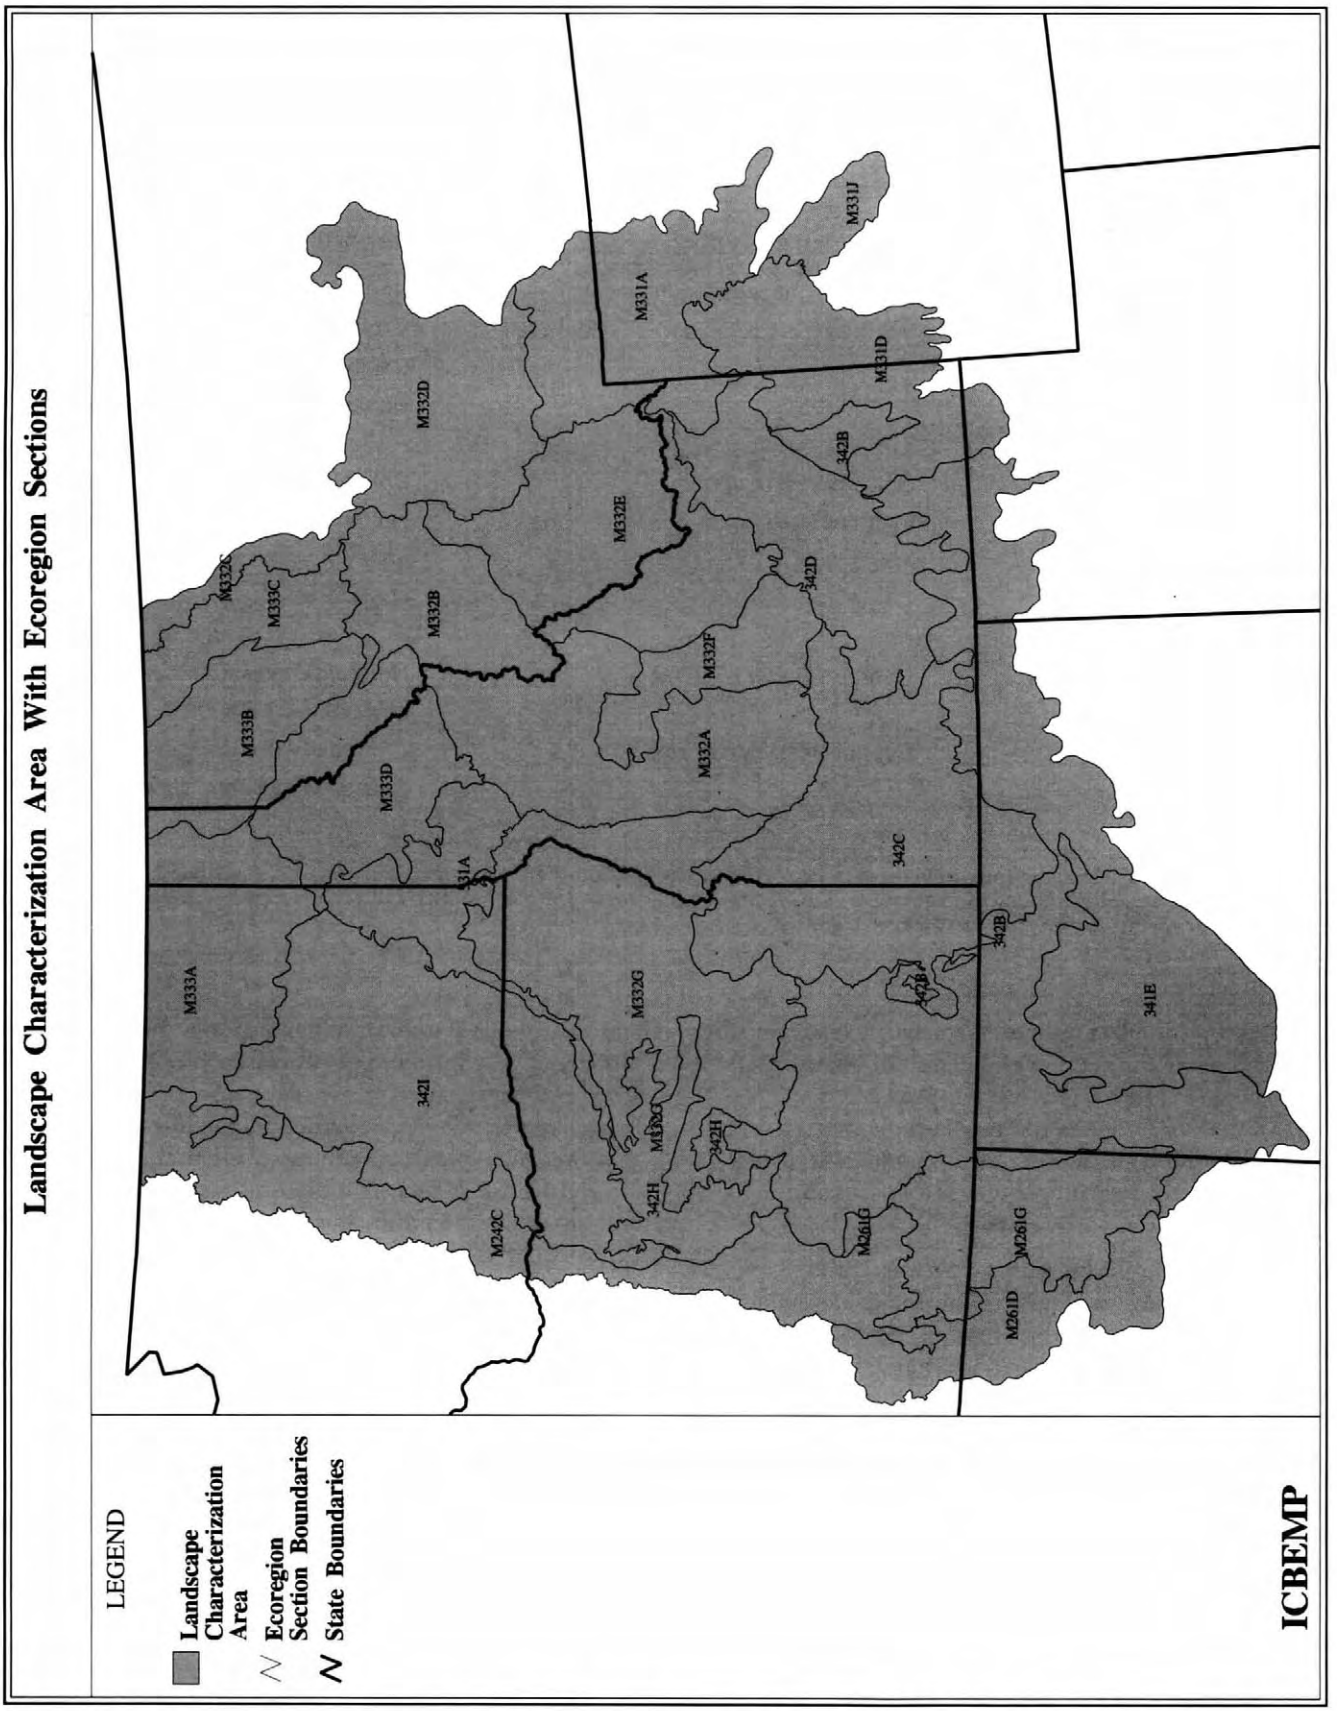
[1] There is not an exact area correlation between Ecological Reporting Units (ERUs) and subbasin groups. The relationship is for the general area. ERU boundaries split some of the subbasin boundaries. There is, however, a direct correlation between the subbasin groups and the generalized subbasin groups.

biological, physical, and disturbance characteristics of an environment over a period of relatively stable climate. The biophysical template provided a foundation for interpreting complex spatial and temporal landscape relationships such as disturbance regimes and vegetation succession, composition, and structure.



The biophysical template develops through the evolution and migration of native biota as they interact with disturbances, geomorphologic processes, geologic parent material, topography, and changing climates. This interaction further develops into interdependent combinations of biotic communities, soil, and hydrologic systems. The biophysical template is the current expression of the collective adaptations of species to competition, disturbances, and the physical environment. It is also the current expression of the soils, landform, and hydrologic system development in response to biotic and geomorphologic processes. Biophysical templates have characteristic succession and disturbance regimes that are governed by the interactions between biotic and abiotic components. The interrelationships among biota, soil, succession and disturbance regimes, and hydrologic systems developed over evolutionary and geologic periods.

Biogeochemical processes involve the productive capacity and chemical relationships of the living and nonliving system components considered as a whole (Barbour and others 1987). These processes are often unique to a biophysical template and are described in terms of accumulation, transfer, transformation, and recycling of chemical components that are associated with biological and physical energy flows (Waring and Schlesinger 1985).

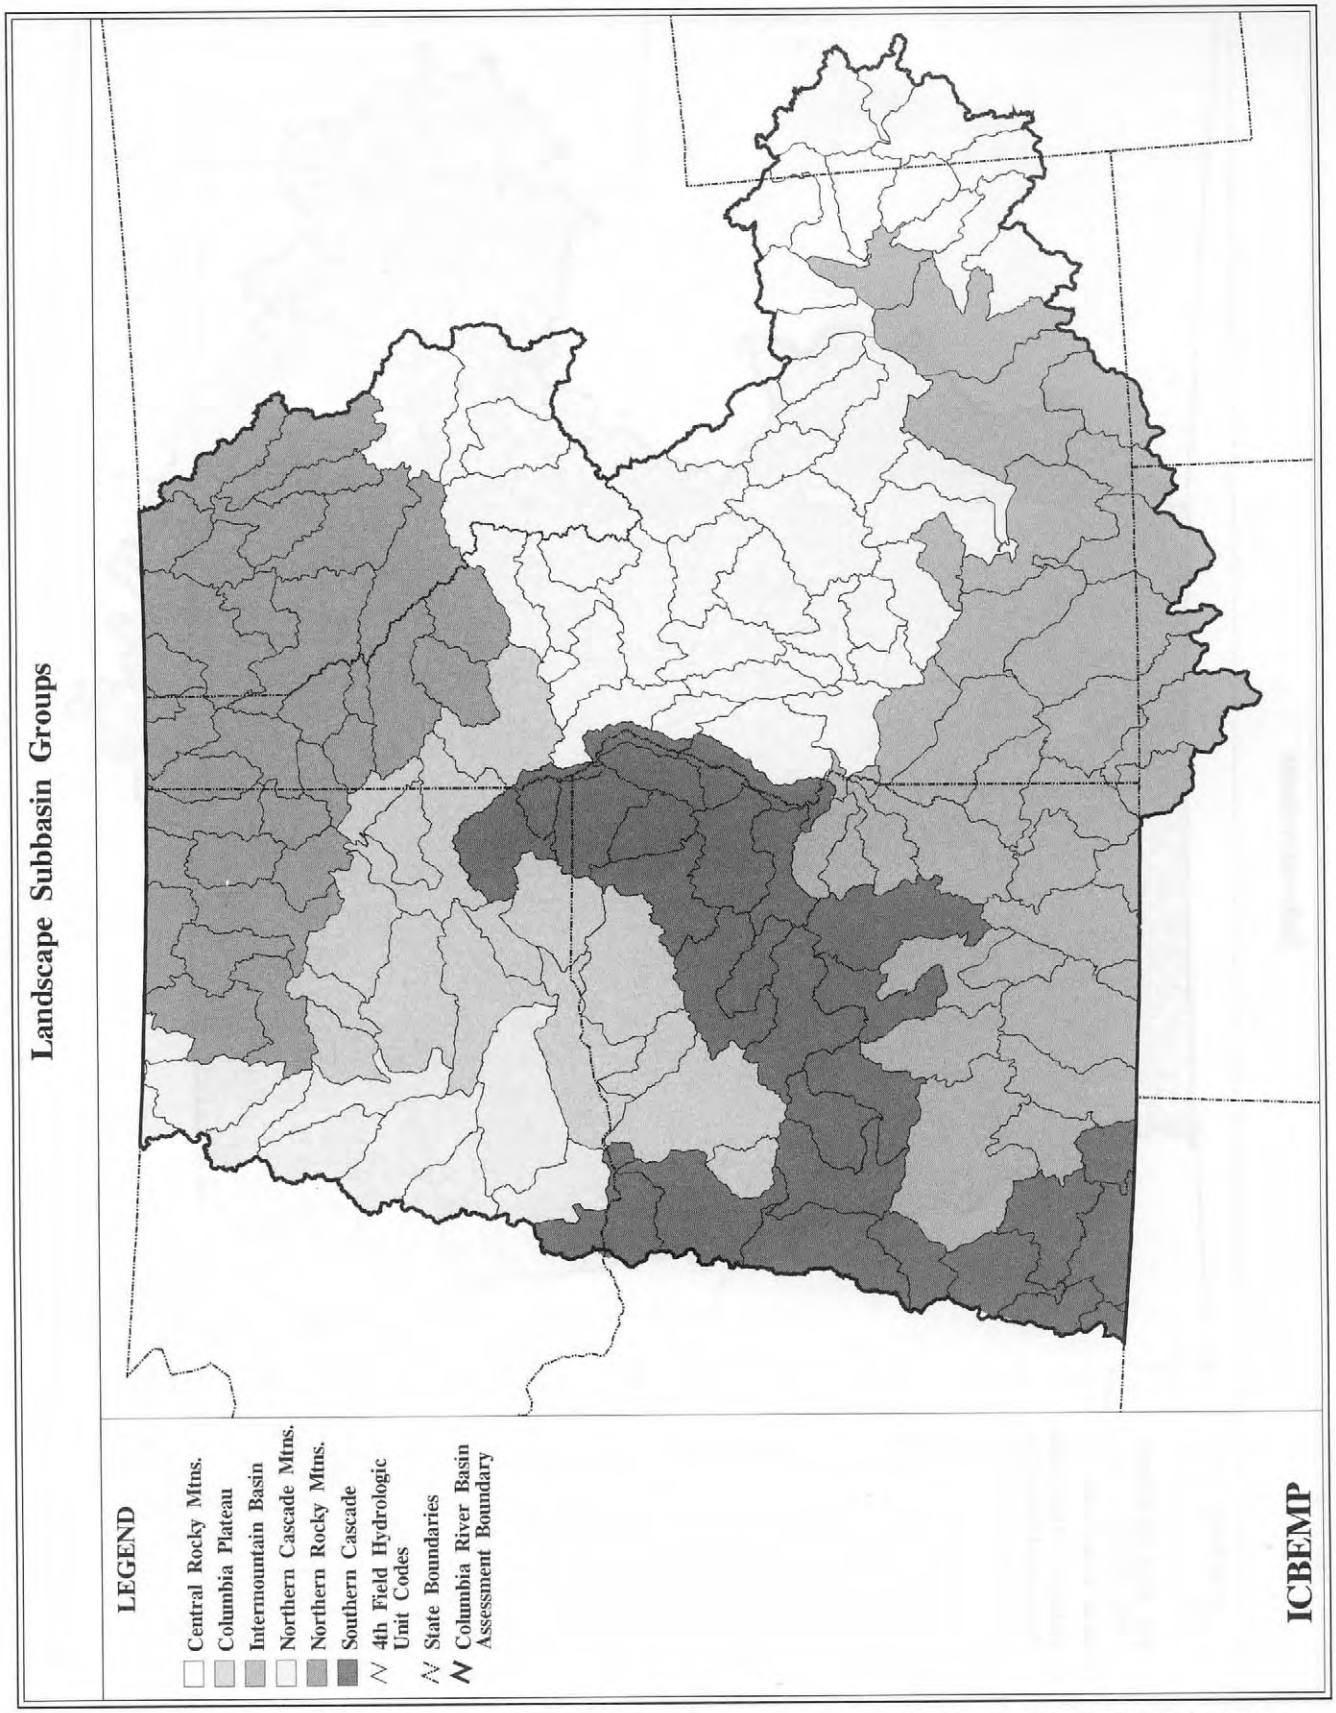
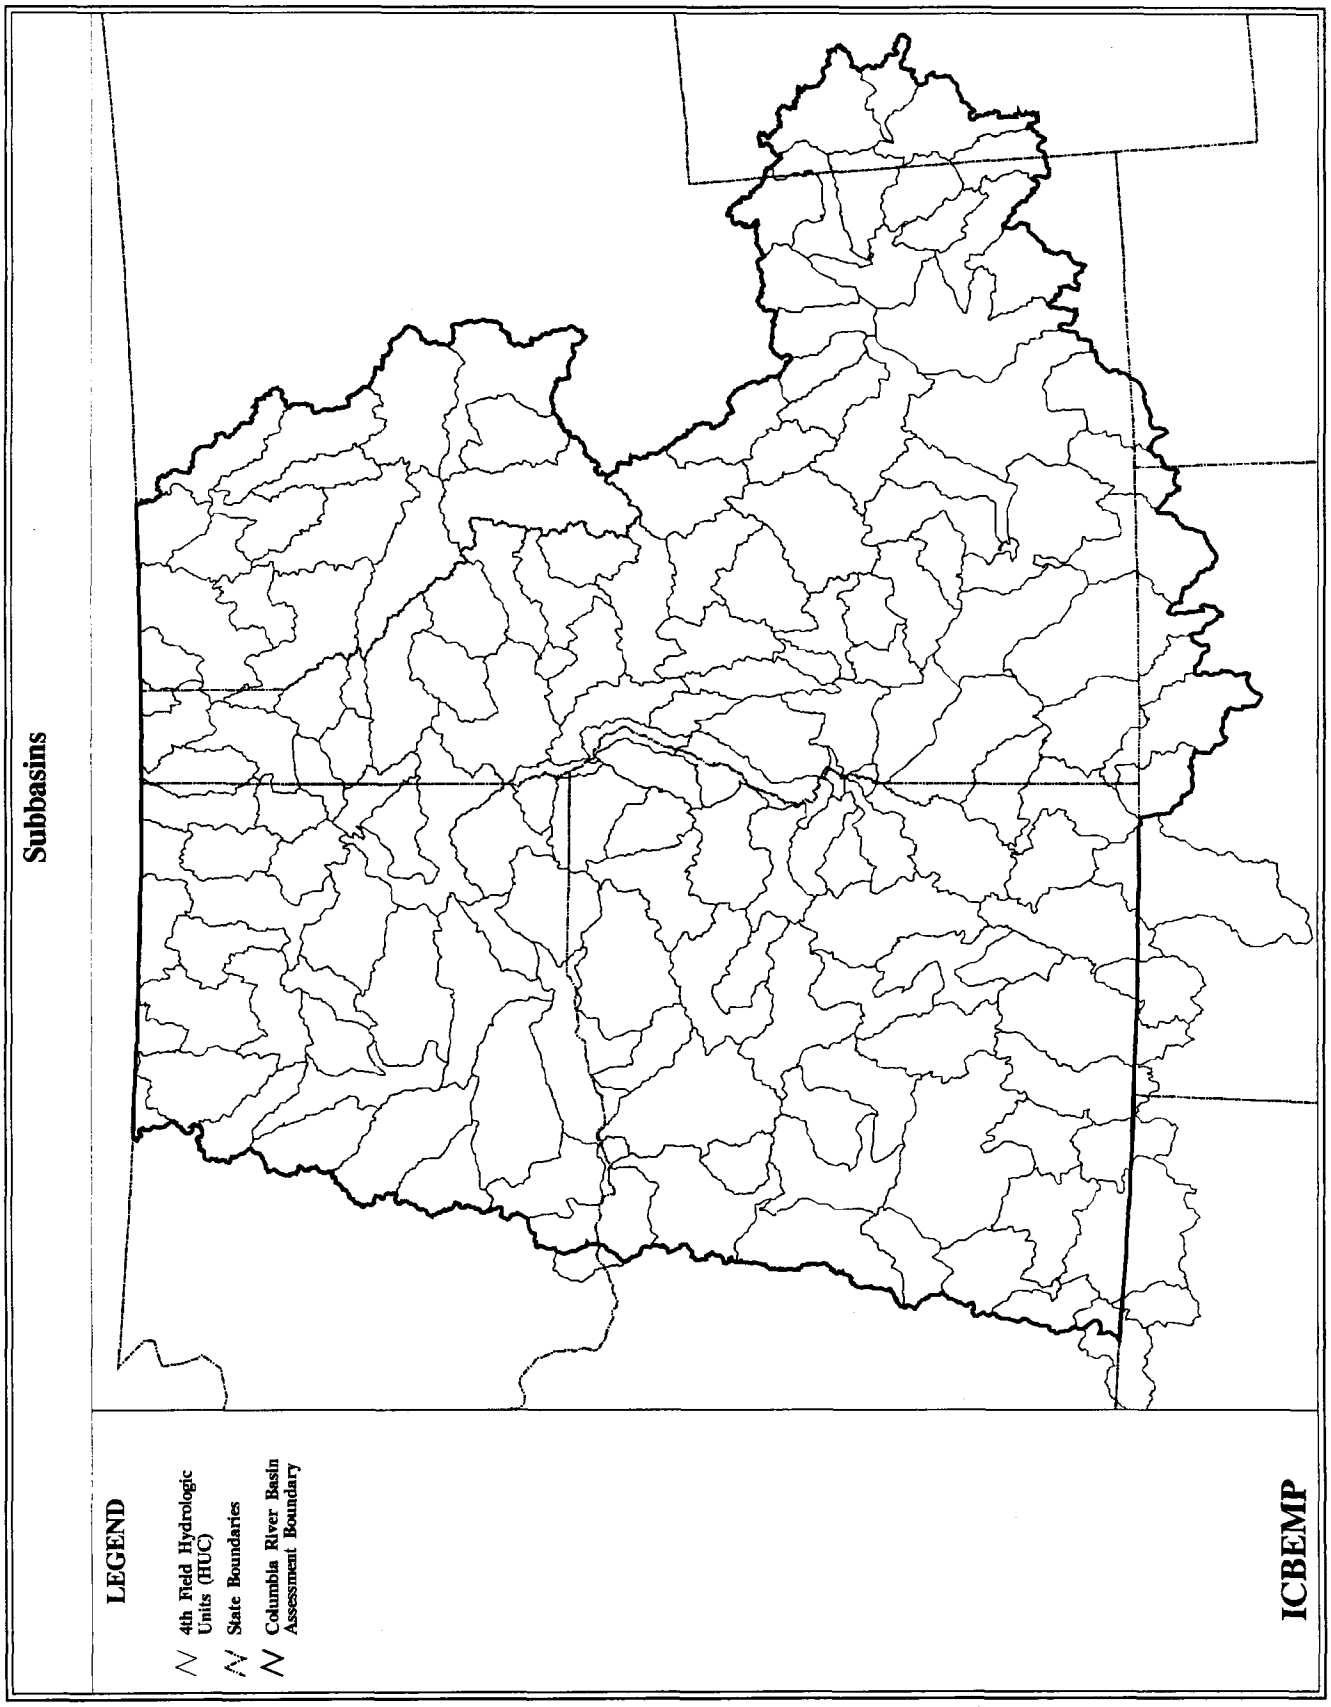


Map 3.1—The landscape characterization area (LCA) for the Basin with ecoregion sections [adapted from McNab and Avers (1994)].



Map 3.2—The assessment area of the Interior Columbia Basin and portions of the Klamath and Great Basins (referred to as the Basin) reflecting Forest Service- and BLM-administered lands.

Map 3.3—The Ecological Reporting Units (ERUs) of the Basin. ERUs are aggregates of subwatersheds (6th field hydrologic unit codes) that generally represent similar terrestrial and aquatic characteristics (see map 3.5).

Map 3.4—The landscape subbasin groups of the Basin. These groups are aggregates of subbasins (4th field hydrologic unit codes) that generally reflect common terrestrial, aquatic, and landscape characteristics (see map 3.6).

Map 3.5—Subwatersheds (6th field hydrologic units) of the Basin. There are 7,469 subwatersheds in the Basin, and they range from less than 500 to more than 85,000 hectares in size. This stratification was a basic data element for addressing aquatic and landscape characteristics.

Map 3.6—Subbasins (4th field hydrologic units) of the Basin. There are 164 subbasins and portions of subbasins in the Basin, and they range from approximately 500,000 to 1,000,000 hectares in size. This stratification was the basic data element for addressing ecological integrity and landscape patterns.

The biophysical template may be altered by any disturbance (or repeated disturbances) that change the relationships between the biotic and abiotic systems. Altered biophysical templates may occur as a result of incremental changes occurring over geologic and evolutionary periods, or they may occur as a result of catastrophic geomorphologic events. Dynamic equilibrium or balance, and thus predictability, is maintained when incremental changes occur slowly over geologic and evolutionary periods. Over such periods, the rate of change is so slow that the trends are difficult to detect unless an appropriate temporal scale is assessed. These changes are often not of immediate concern from a natural resource management perspective, except to provide context. With the exception of catastrophic events (for example landslides and volcanism), long periods (>10,000 years) are needed to affect topography and parent material. Somewhat shorter timeframes (500-10,000 years) are associated with changes in climate and associated edaphic processes. Catastrophic events usually result in disequilibrium for at least a short period, but equilibrium returns within a predictable time. Because they occur infrequently, catastrophic events are generally only of concern to resource managers after they occur.

It is important to emphasize that human interaction with other species and the environment has been a very important part of the development of biophysical templates over the course of human evolution. Humans have become very effective at altering biophysical templates by altering food web relationships, hydrologic cycles, and carbon-nutrient cycles; application of human technological energy often disrupts interrelated functions and processes. Human-related activities that can alter the biophysical template include invasions by exotic species, extirpation of populations, soil erosion, severe alluvial events, wildland conversion to urban or cropland uses, or the release of toxic pollutants into the air, soil, and water.

In wildland environments, human-induced effects might dominate the succession and disturbance processes for relatively short timeframes, but in the long term, these processes will frequently overpower the "artificial" states that are maintained by subsidies provided by society. For example, mechanical, technological, and other forms of human energy may change the relationships of biophysical and disturbance conditions. These human-induced changes include efforts to exclude fire, floods, insect and disease mortalities, and other disturbance events, and produce commodities such as livestock, big game, forest products, and visual conditions from forests and rangelands. Since Euro-American settlement of the Basin, most of these efforts have been conducted in ways that have simplified landscape conditions (that is, composition, structure, and function). These changed systems typically have higher or lower quantities of on-site biomass than is consistent with their biological capability.

Terrestrial and aquatic communities frequently change within a single year in response to natural disturbances (such as fire, drought, tree windthrow, animals, insects, pathogens, avalanches, floods) and anthropogenic disturbances (such as hunting, fishing, logging, and livestock grazing activities). The subsequent changes in the biotic community, hydrologic system, or soil condition are referred to as secondary succession, stand dynamics, state change, or disturbance recovery (Barbour and others 1980, Gebhardt and others 1989, Oliver and Larson 1996). These types of disturbances are considered secondary disturbances because they do not change the primary evolutionary relationships among the biotic, climatic, hydrologic, pedogenic, geomorphologic, and geologic systems.

Essentially, any factor that changes the ecological cause-and-effect relationships will alter biophysical relationships. This can effect evolutionary adaptations, co-evolutionary relationships, biogeochemical processes, and biophysical development. When humans change biophysical conditions by altering topography, parent material, or soils, introducing exotic species, or causing species or genera extinction, they alter biophysical relationships. Modifications of biophysical relationships, in turn,

change biogeochemical processes. Altered systems respond differently and less predictably to disturbances than do unaltered biophysical templates.

Any exotic species, including plants, animals, and pathogens, that have substantial effects on species composition can alter biophysical conditions. Toxic pollutants can also change the environment of the native biota and thereby alter biophysical relationships. Erosion of soil or removal of soil can alter the site capability and potential for native species. Once the environment, particularly the topsoil, is disrupted in a major way (such as by tilling or mining activities) there is little chance of recovering the cause-and-effect relationships of the native system within human timeframes, even after intensive restoration.

Roads may directly alter biophysical conditions as a result of their effects on soils. In addition, roads may indirectly affect biophysical relationships because they often act as conduits for the spread of exotic plants, they may increase the potential for fire ignitions, and they disrupt hydrologic regimes.

Geographic areas (that reflect differences in climate), potential vegetation types (that reflect moisture and temperature regimes), and landforms (that reflect geomorphologic processes) provide meaningful stratifications for understanding broad-scale biophysical templates and the mechanisms behind mid- and fine-scale landscape patterns. Within a geographic area, we commonly used potential vegetation groups (PVGs) as indicators of biophysical templates (see appendix 3-A for detailed descriptions of the PVGs).

Historical Range of Variability (HRV)

The HRV (Morgan and others 1994) provides a means of understanding biophysical templates and the biodiversity relationships of paleoecological and historical systems. The HRV incorporates the relationships between the energy of the system in terms of biomass accumulation (for example growth, development, transpiration), and the processes of disturbances that convert or physically transport biomass (for example herbivory, fire, avalanche, and flood). Thus, the HRV can serve as a tool for understanding the causes and consequences of change in ecosystem characteristics over time (Morgan and others 1994). Not only can HRV be used to help describe native systems, but it can also serve as a benchmark for understanding the effects of human-induced changes of biophysical templates. We simulated the HRV by developing pre-Euro-American settlement succession/disturbance models for each potential vegetation type (PVT; see appendix 3-A for descriptions of PVTs) in the Basin and simulating change over a 100- or 400-year period from the historical vegetation map (Long and others 1996).

Morgan and others (1994) suggested that the HRV should be assessed for a time period characterized by relatively consistent climatic, edaphic, topographic, and biogeographic conditions. For this assessment, we were most interested in the HRV of contemporary ecosystems. Thus, we focused our assessment of HRV on the biophysical templates that existed during the period between the beginning of the current climatic regime and prior to Euro-American settlement. Mack and others (1983) suggested that the present macroclimate emerged approximately 2,700 years before present. Furthermore, it has been suggested that present plant communities endemic to temperate environments (Schoonmaker and Foster 1991) and the Basin (Mehringer 1996) have been in some state of equilibrium with the environment since about 2,000 years before present. Although the "Little Ice Age" occurred from about 1450 to 1850 A.D. (Wahl and Lawson 1970, Webb and Bartlein 1992) and undoubtedly altered plant communities and their environment, it did not substantially affect the general trend in plant communities (Mehringer 1996; Webb and Bartlein 1992) or disturbance regimes (for example, fire) (Barrett 1995) characteristic of the warmer, post-glacial climates. At the time of Euro-American settlement, some plant communities, environments, and fuels were characteristic of the cooler, moister conditions of the "Little Ice Age" and had not yet adjusted to the warmer environment. Although the "Little Ice Age" shifted the equilibrium of

species ranges and disturbance regimes, it did not result in extinctions or substantial changes in ecological relationships. Thus, prior to Euro-American settlement, broad-scale biophysical relationships in the Basin had been relatively stable for nearly 2,000 years.

We recognized Native American peoples' use of fire as a disturbance process that influenced the HRV, as these cultures have had an integral role on the landscape for at least the last 2,000 years (Mehringer and others 1977, Woods and Horstman 1996). Although Native American cultures were affected by substantial decreases in population as a result of the introduction of Old World diseases during the pre-contact era (between the years 1500 and 1800)(Denevan 1992, Woods and Horstman 1996), their ignitions still substantially augmented wildfires over vast areas of the Basin throughout much of the Nineteenth Century (Barrett and Arno 1982, Ross 1981, Shinn 1980). Their effects on the landscape were especially noticeable near grasslands, low-elevation forests, and in or near major valleys or other significant settlement locations, resource acquisition areas, and travel routes (Barrett and Arno 1982). However, it could also be argued that when considering the relationship between fuel continuity and lightning ignitions of the 2,000 years prior to Euro-American settlement, broad-scale fire regimes would not have been measurably affected by Native Americans. Furthermore, morphological and ecological evolution in plants can occur relatively rapidly as demonstrated by ecotypic variation, perhaps within several decades or less (Woodward 1987). Consequently, it seems that most flora, and probably fauna as well, had adapted to the widespread use of fire by Native Americans over the last 2,000 years.

Although humans have been key drivers of many landscape processes in western North America, their recent historical (that is, post-Euro-American settlement) influences were not considered as part of the HRV. Subsequent to Euro-American settlement, anthropogenic disturbances began to simplify many systems because many endemic plant and animal species had not co-developed with widespread, intense, or frequent human disturbances, as had the endemic species of Africa, Europe, and Asia. The rate of change in ecosystem characteristics is at least as important to the concept of HRV as the magnitude of change (Morgan and others 1994). Humans have the capacity to rapidly alter biophysical environments at a rate and in a spatial array that prohibits many species from dispersing into suitable habitats, or adapting to altered regimes. Thus, in order to provide a context for interpreting the causes and consequences of change of ecosystem characteristics through time, we chose to assess the HRV prior to the period of the most rapid and intense changes, that is at the onset of the Euro-American settlement of the Basin.

The HRV provides a means of referencing the current conditions and differences among various future land-management scenarios. However, land managers may not want to target the HRV as a management objective because it does not account for the influences that humans have had on their environment, nor the values that humans want to produce from their environment (Morgan and others 1994). Humans have commonly modified systems so that food, fiber, visual conditions, wildlife habitat, or other forms of biomass can accumulate. In some circumstances, humans have altered the biophysical template to such an extent that historical disturbance regimes, and landscape compositions and structures are no longer achievable. Although land managers can attempt to mimic the historical system, the HRV can only be obtained within those biophysical systems that have not been substantially altered. In systems that have been altered, the relationships have changed and restoration of historical conditions may be impossible or prohibitively expensive. In addition, humans often desire to process biomass in timeframes that are different from the disturbance regimes of the HRV. Even on lands where the objective is not to extract resources but instead to manage for "natural" processes (for example in wilderness and semi-primitive areas), the size, intensity, or pattern of disturbance events (such as fire) may occur at a scale that is considered unacceptable by society.

Of what value then is the HRV? Without an understanding of biophysical templates and their associated disturbance and succession regimes, it would be difficult to comprehend the cause-and-effect relationships of resource extraction or the responses of biodiversity to system changes. The HRV is useful as a benchmark for assessing or monitoring effects of land management relative to the departure from historical conditions. These departures can be used as a reference against which to evaluate change and to help identify risks to ecosystem sustainability (Morgan and others 1994). The HRV is also useful for assessing or monitoring effects of land management relative to biogeochemical processes, succession, disturbance, and hydrologic regimes. This can help land managers understand tradeoffs between different management strategies with respect to resource production capability, disturbance events, environmental effects, and changes in regimes.

The HRV provides a tool for land managers to design better approaches for the production of resources and the conservation of biodiversity that work more effectively within the biophysical templates, whether the templates have been changed or remain intact.

The HRV also provides a means for understanding the relationships between native species and associated biophysical templates. For example, the areal extent and pattern of a particular habitat can affect the colonization potential of individuals (including exotic species), persistence of individuals, persistence of populations, and the number of species within a landscape (Morrison and others 1992). Three indices of vegetation change are required to better understand the effects of vegetation trends on ecosystem dynamics. First, the proportional change in areal extent of a vegetation type (that is, class change) is informative because it quantifies the change of that vegetation type relative to itself. Second, the proportional change in area of a vegetation type relative to the landscape (that is, landscape change) is also enlightening, because it factors in the dominance of that vegetation type within the landscape. However, substantial areal changes of a vegetation type may still not have substantial ecological ramifications, if those changes occurred within some expected range of variation in which biological entities and processes have evolved (that is, HRV). Consequently, only by comparing the magnitude of change to some historical range of expected conditions can we fully ground the ecological implications of vegetation trends on ecosystem structure and function. Taking this into account, we developed a departure index, which compared current conditions to the HRV.

The conservation of biota at the region or landscape scale requires an understanding of population dynamics and some notion of how various biota may respond to environmental conditions at the scale of interest. Unfortunately, scientists and managers currently have, at best, only vague understandings of how the wide variety of species and populations may respond to varying vegetation patterns within the Basin. In lieu of such information, a premise of this chapter is that the endemic biota of the Basin will have the fewest risks to population persistence if regional and landscape vegetation patterns approximate those in which the biota have adapted over the last two millennia.

Estimation of broad-scale habitat departures from historical ranges of conditions provides an index of broad-scale vegetation changes in the context of natural systems and provides a means of developing coarse-filter inferences of the risks to species persistence (Hunter 1991, Hunter and others 1988). A primary assumption of this coarse-filter approach to habitat assessment is that the conservation of the areal extent of a community or habitat within its historical range could allow species adapted to that range to persist into the future.

In this chapter, the current broad-scale habitat availability within a region or a landscape was compared to the range of conditions expected historically (that is, HRV). It was assumed that a species' persistence within that geographic area was not at risk if the current area of that species' primary habitat (as described in Terrestrial Ecology, Chapter 5 of this document) fell within the

median 75-percent range of the historical data.[5] Risk to persistence increased substantially when habitat availability fell below the median 75-percent range of the historical data. Conversely, persistence likelihood within a geographic area increased as habitat availability exceeded the median 75-percent range of the historical data. Thus, the HRV not only provided a means of grounding habitat trends, but was also helpful in formulating inferences pertaining to the population persistence of species for which little is known.

Succession and Disturbance Regimes

An understanding of spatial relationships of succession and disturbance regimes provides an integrated way to comprehend response to disturbance and resiliency of the system. A regime provides an integrated classification of the relationships of energy, hydrologic, carbon-nutrient, food web, and evolutionary adaptation processes.

Short-term, secondary changes are commonly of more interest to people concerned with natural resource management, since they occur within temporal scales to which society can more easily relate. This is in contrast to primary successional responses which usually develop over much longer timeframes and affect the equilibrium relationships of biotic, climatic, hydrologic, pedogenic, and geomorphologic processes (Allen and Hoekstra 1992, Barbour and others 1980, Forman and Godron 1986, Jenny 1980, Naveh and Lieberman 1994, Rosgen 1996).

The successional response of communities, soil, and hydrologic systems to disturbances are inherent within the limits of a biophysical template. Parent material, topography, climate, associated biota, and adaptations associated with patterns of disturbance define the biophysical template that controls succession and disturbance processes. We refer to this part of a biophysical template as the "succession/disturbance regime." The succession/disturbance regime is the expected spatial and temporal response of biotic communities, soil, and the hydrologic system for a biophysical template.

Various types of disturbance regime classifications have been developed. Fire regimes have been developed by Agee (1994), Christensen (1985), Covington and Moore (1994), Heinselman (1983), Huff and others (1995), Morgan and others (1995), and Williams and Rothermel (1992) that use fire severity, frequency, or behavior as classification variables. Forest insect and pathogen regimes have been characterized by Filip and others (1996), Harvey (1994), Hessburg and others (1994), and Lehmkuhl and others (1994) that emphasize response to specific agents, regime response to groups of insects or pathogens with similar effects, and general insect and pathogen roles in different kinds of environments. Soil processes in relation to disturbance have been characterized by Harvey and others (1994a).

Successional cycles (similar to regimes) following fire and associated disturbances have been characterized by Agee (1995), Covington and others (1994), Fischer and Bradley (1987), Loucks and others (1985), Runkle (1985), and Shiplett and Neuenschwander (1994) using potential vegetation, length of cycles, or type of response to classify response. Oliver (1981) and Oliver and Larson (1990, 1996) classify stand dynamics based on types of forest structural development and frequency of disturbance. Multiple stable states have been described by Laycock (1991) and Tausch and others (1993) that classify stable communities in relation to history of grazing, paleoecological climate change, or invasion of exotics. Archer and Smeins (1991) and Bailey and others (1996) characterize response to grazing disturbance based on temporal or spatial patterns, and associated effects.

For this assessment, we provide a classification that integrates aquatic and terrestrial systems, and complexes of disturbance. We classified succession/disturbance regimes according to: (1) the severity of the disturbance relative to the subsequent change of community composition

[5] The median 75 percent of the historical range indicates the value is within 75 percent of the range from minimum to maximum. This excludes 12.5 percent of the range on each end.

and structure; (2) the time interval between disturbances; (3) the resiliency or rate of community development in response to the disturbance; and (4) the mosaic created by disturbance through time.

Changes in a biophysical template will subsequently alter a succession/disturbance regime. Laycock (1991), Lockwood and Lockwood (1993), and Tausch and others (1993) developed various concepts pertaining to community thresholds and successional response in time and space. A conceptual response of succession and disturbance to a biophysical template is presented in figure 3.6. Example "a" displays the HRV or native dynamics of a community prior to the effects of widespread and rapid human-induced change. The community represented in example "a" experiences frequent disturbances that generally maintain its composition and structure by consuming biomass that accumulates between disturbances. In figure 3.6 example "b," the succession/disturbance regime is changed through the investment of human energy, which increases the interval between disturbances such that biomass accumulates and is then used to produce particular values or commodities. The biophysical template has not been changed in example "b," and the system can return to the community and succession/disturbance regime of example "a" given similar disturbances and intervals as in "a." An example of this scenario includes the exclusion of fire from the dry forest PVG with harvest of the understory at intervals two to three times the HRV underburn-fire interval. In this same example, the succession/disturbance regime can be changed to reduce the interval between biomass reductions (for example by grazing), without altering the biophysical template.

In figure 3.6 example "c," the biophysical template has been altered, thus producing a different community that has a shorter interval between disturbances and an altered production capability. For example, the introduction of exotics such as cheatgrass (*Bromus tectorum*) in the dry shrub PVG, the conversion to dryland agriculture, or the introduction of white pine blister rust (*Cronartium ribicola*) in the moist and cold forest PVGs, has eliminated native species from the community. In this situation, neither protection nor disturbance will return these systems to their native regimes reflected by figure 3.6 example "a." However, a substantial investment of human energy to control disturbance and re-establish perennial species might allow the native system (example "a") to be approximated.

Figure 3.6 example "d" reflects a system where human energy is used to remove disturbance (for example, fire exclusion) or to produce high levels of biomass (for example, big game hiding cover or

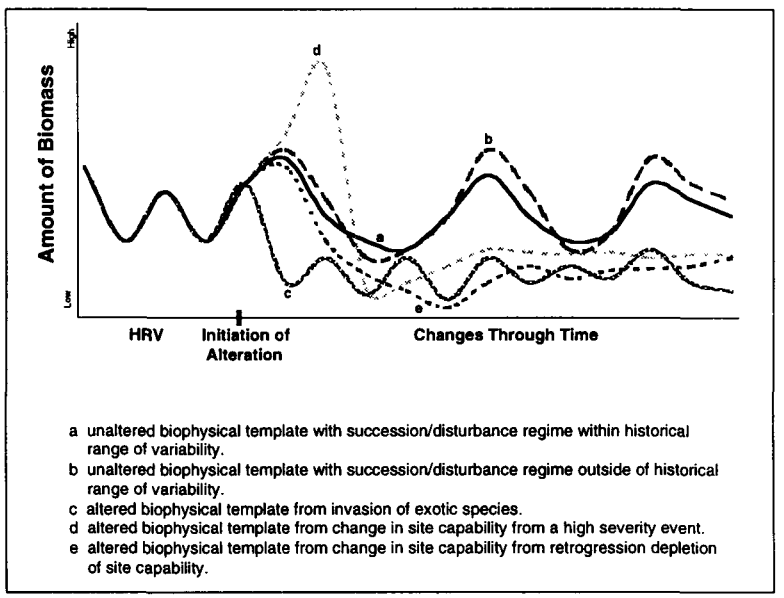


Figure 3.6—Conceptual diagram of the relationship of succession/disturbance regimes to the biophysical template, and the effects of alteration in the biophysical template [adapted from Tausch and others (1993)]. HRV refers to the historical range of variability and is defined as the pre-Euro-American settlement or "native" regime.

cover to maintain a particular visual condition). Eventually, the biogeochemical potential of these systems (that is, biotic and abiotic processes) is substantially disrupted as a result of a severe disturbance with an associated loss of soil and nutrients, and often an associated invasion of exotic species in severely disturbed environments. For instance, the eventual build up of biomass (that is, fuel) is so exaggerated that the ability of society to exclude high-severity fires is reduced.

In figure 3.6, example "e" represents a situation in which disturbances are very frequent (for example, excessive grazing) and do not allow biomass accumulation. Over time, the reduction of biomass disrupts nutrient cycling and is inadequate for soil protection. The subsequent erosion and loss of soil nutrients lessen site productivity as in example "d." In general, the more the biophysical template is altered, the less predictable the responses of the system are to disturbances, and the more human-provided energy subsidies are required to sustain resource outputs and biodiversity.

Landscape Patterns

Landscape patterns are ultimately a consequence of climatic, geomorphologic, and succession/disturbance processes (Forman 1995, Forman and Godron 1986, Oliver and Larson 1996). Geomorphology determines the patterns of soils and topography (that is, slope, aspect, and elevation). Climate and geomorphology are interdependent, and thus climatic patterns influence geomorphologic patterns. The converse is also true. The pattern of succession/disturbance regimes is a consequence of geomorphologic and climatic patterns, as well as biogeochemical processes. Succession/disturbance regimes can be mapped at any scale by classifying the type of landscape pattern and relating each regime to biogeochemical and landform characteristics.

Landforms are highly correlated with the dominant processes (that is, geomorphologic, climatic, and anthropogenic) that constrain the dynamics of landscapes. Landforms are subsequently associated with the spatial orientation of landscape mosaics within the Basin. Ownership patterns and land uses are also correlated to landform. For example, FS- and BLM-administered lands within the Basin were dominated by the foothills and mountains, and plains broad-scale landform types (table 3.2).

In most landscapes, the profile of landforms from the watershed divide to the drainage bottom follows a generalized and consistent pattern: transition from ridge to slope, to footslope, to terrace or plain, to toeslope, and then to the channel zone/draw. Different types of landscapes may vary in the profile of these landforms, both in presence of the different landforms and in their individual size, shape, slope, aspect, and juxtaposition to other landforms. However, we speculate that this generalized pattern occurs on all landscapes, regardless of size (for example subbasins, watersheds, subwatersheds). The shape and extent of the profile vary according to the broad-scale landform.

Table 3.2—Areal distribution of broad-scale (coarse) landforms[1] types on lands administered by the BLM and FS.

Landscape Landform	BLM/FS Land Ownership Area[2] (percent)
Foothills	12
Foothills and Mountains	39
Mountains	9
Plains	35
Mixed[3]	5
Total	100

[1]Dominant landform or mixture of landforms by subbasin.

[2]Data used from EIS data version; the area evaluated for the EIS data version is slightly larger in extent than is the areal extent of the earlier Assessment data version.

[3]Mixed = Plains, Foothills, and Mountains.

For example, in plains landforms, the landscape profile is extended and the ridge and channel zone/draw landforms may be many kilometers apart. Conversely, ridge and channel zone/draw landforms may occur within 1 kilometer of each other in the mountains broad-scale landform. Although landscape patterns are ultimately defined by biogeochemical processes, there are strong correlations between pattern and composition of potential vegetation types, landforms, land uses, and succession/disturbance regimes.

Biogeochemical Processes

Biogeochemical processes involve the transfer of chemical elements between biotic and abiotic components of an ecosystem. These processes can be described in terms of the accumulation, transfer, and recycling of chemical components associated with biological and physical energy cycles. At the regional scale, our assessment of biogeochemical processes focused on primary productivity, and the flow of carbon, nutrients, and water through the ecosystem. The assessment of biogeochemical processes may reveal the fundamental biological, physical, and chemical relationships responsible for vegetation dynamics. Quantifying and mapping the spatial distribution of fundamental processes such as photosynthesis, transpiration, and respiration can help identify areas that are productive; areas where carbon accumulates; and areas where vegetation may be physiologically stressed by water or nutrient deficiencies, insects, disease, or herbivory. Biogeochemical processes were simulated using a mechanistic biogeochemical model (BGC) (see Keane 1996) to provide a coarse summary of the productivity and the ecophysiological robustness of historical, current, and projected future vegetation under several climatic conditions.

Proper Functioning Landscapes

The investment of energy via human activities and subsidies that alter the rates and routes of key ecosystem processes, will likely produce landscapes having higher tendencies of equilibrium. A function or process that has been essentially removed from a system must be artificially provided in order to restore and maintain equilibrium within the context of the key ecosystem processes (Allen and Hoekstra 1992). Assessment and management that strive to achieve ecological equilibrium can be accomplished in two ways. An inherently complex strategy would be to develop a thorough understanding and a restoration plan of the impaired key ecological processes and functions. Alternatively, a simpler strategy would include an understanding and a restoration plan of the succession/disturbance regimes, life forms, and structures that initiate trends toward equilibrium. A value of the second approach is that it provides a means of rapid assessment of the landscapes composing a region, such that the context of the region can be used to plan the needs of its component landscapes.

In contrast to a state of disequilibrium (fig. 3.4), society can restore and maintain functioning ecological processes at appropriate landscape scales (fig. 3.7). We define "proper functioning landscapes" as those landscapes whose processes are in equilibrium, such that the rates and routes of key processes (including disturbance) are resilient and predictable. In other words, proper functioning landscapes contain the patterns and composition of succession/disturbance regimes, life forms, and structures that provide for ecological equilibrium. In essence, pattern and composition act as a surrogate for the complex relationships of the many processes and elements.

The concept of a proper functioning landscape provides a means of integrating human needs and values with ecological processes. The concept also provides the means of producing

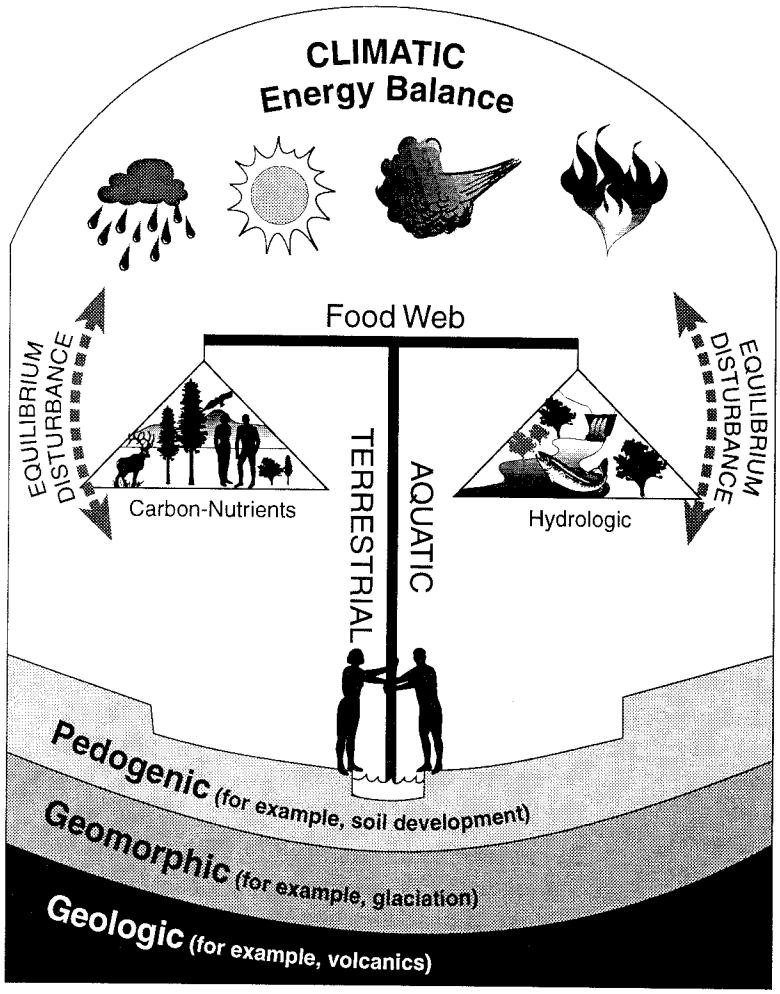

Figure 3.7—Schematic of proper functioning landscapes and re-establishment of equilibrium processes.

a more stable and predictable environment, while conserving biodiversity (Allen and Hoekstra 1992, Hunter 1991). Cumulative effects of humans on ecological processes can be ranked (table 3.3). Ecological functions can then be prioritized for restoration. Production of commodities emerges from this paradigm in response to ecological consequences, rather than as disruptions to system capabilities that result in disequilibrium. For instance, you can pick apples either by using a ladder or by cutting down the tree. Both methods result in an annual crop, but cutting down the tree results in loss of system capability. Assessing proper functioning landscapes provides a framework for a "contextual opportunity and risk analysis", and reiterates the ideas presented by Haynes and others (1996). In addition, the nature of the analysis for proper functioning landscapes provides an iterative system that can be "best fit" for achieving resource management goals within biophysical capabilities and inherent disturbance processes. An understanding of the means in which succession/disturbance regimes and general landscape patterns relate to different wildland management scenarios provides a basis for integrating the key ecological processes with anthropogenic disturbances.

The concept of the proper functioning landscape supports the concepts of sustainability, ecosystem health, and ecological integrity by providing a platform for their spatial integration. The concepts of ecosystem health, sustainability, and ecological integrity have typically been applied to generic ecosystems (such as forest, rangeland, or aquatic), or to specific elements of specific ecosystems (for example, endangered species such as the grizzly bear, spotted owl, or anadromous fishes), but not at a landscape scale. These concepts are difficult to integrate within a landscape that includes anthropogenic processes because they often conflict with one another. Management strategies intending to restore the "health" of one component can have deleterious effects on the health of another component.

Table 3.3 —General categories of human technology and their effects on ecological systems. The rankings are relative and are used simply to indicate intensity and spatial extent of effects on disruption of system processes.

Conceptual Models of Natural Resource Management

We believe that there are two primary paradigms of managing natural resources within wildland settings. The contextual ecological paradigm uses a multi-scaled approach to address opportunities and risks within a landscape context. The independent element paradigm develops production, conservation, and restoration objectives for a single ecosystem element as though it were isolated from all other elements. We refer to these as the ecological and independent (also referred to as traditional) management models, respectively.

Ecological Model

Contextual opportunity and risk analysis using a landscape ecology approach provides a framework to: (1) identify risks at the regional scale for landscapes that have remnant populations of species, high quality habitats, high quality watersheds, or that are otherwise important from a biodiversity perspective; (2) identify conservation and maintenance strategies to sustain the values of high risk landscapes; (3) identify restoration and production opportunities that do not present risks to landscapes within a region; (4) identify restoration and production opportunities that can be scheduled spatially or temporally into low risk landscapes; and (5) identify restoration or production activities that can be scheduled temporally into high risk landscapes as adjacent landscapes are restored, or as particular elements (for example, endangered species) recover. A contextual opportunity and risk analysis requires a multi-scale assessment process (fig. 3.8) involving: (1) assessing trends, risks, and opportunities related to elements and landscapes, and their context within subregional and regional scales (that is, regional and subregional assessments), and (2) assessing the risks and opportunities within landscapes in relation to

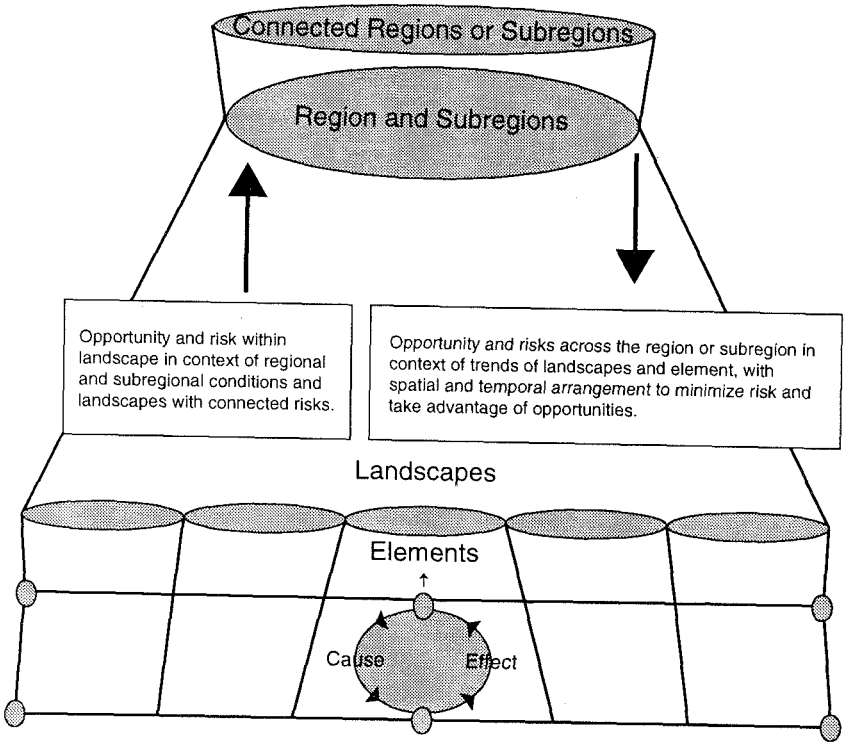

Figure 3.8—Contextual opportunity and risk management with a hierarchical landscape framework.

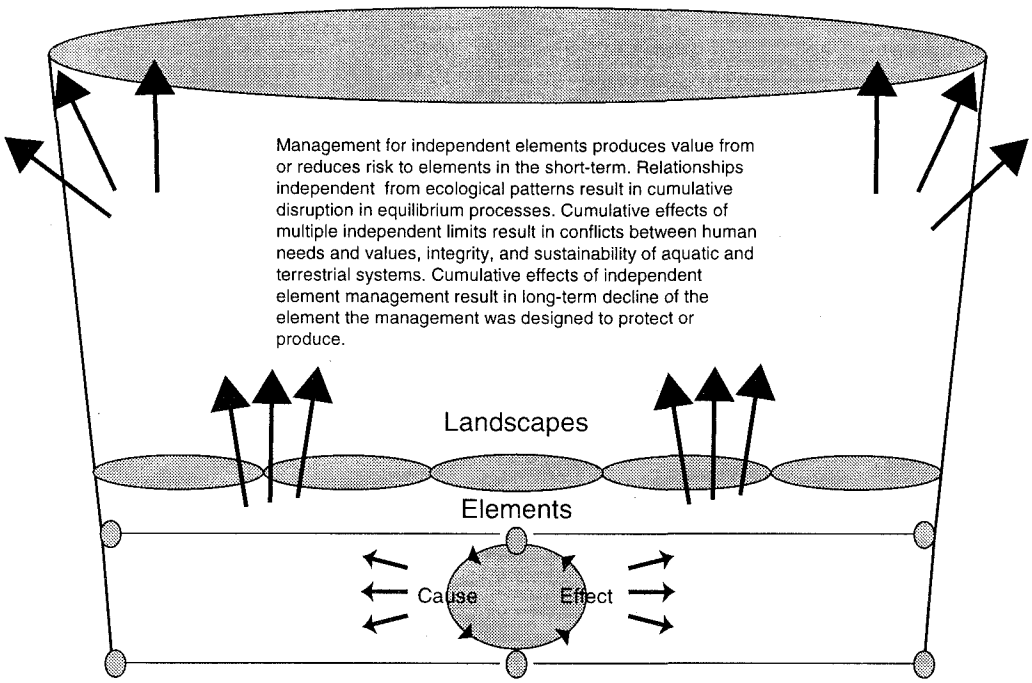

Figure 3.9—Independent element management without a hierarchical landscape framework.

connected landscapes and the context of the region or subregion (that is, landscape assessment). Regional and subregional assessments provide the context for individual elements and landscapes, whereas landscape assessments provide an understanding of mechanistic relationships. Thus, a multi-scale assessment provides the context and mechanisms, as well as the opportunities and risks within the area being studied. As a result, a multi-scale foundation can be developed to strategize a means to spatially and temporally arrange conservation, restoration, and production priorities, thus taking advantage of opportunities, while minimizing risks.

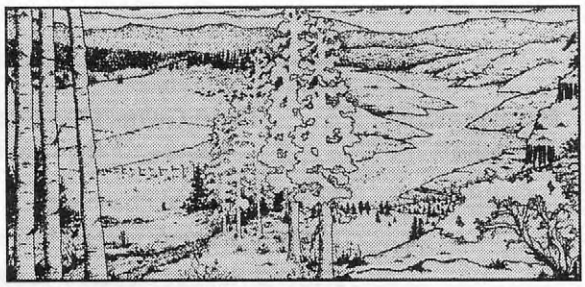
Independent Model

Independent element limits serve as constraints to conservation, restoration, or production activities that were not developed in concert with other elements at multiple scales (region, subregion, landscape), or in association with ecological processes. The independent element limit approach attempts to manage risks and deleterious effects through a "take" or "protect" approach wherever that element occurs (fig. 3.9). Such a strategy results in the cumulative disruption of ecological processes. This has been the traditional management model used for both commodity production and establishment of reserves.

Independent limits are designed to meet specific objectives for human needs and values such as commodity production, the conservation of rare elements, and the preservation of clean air and water. Examples include: socially and economically driven objectives for timber harvests; stream or riparian buffer widths to limit commodity activities; fire exclusion; tree or snag retention guidelines within harvest units (numerical); forest regeneration requirements and limitations of harvest unit size as directed by the National Forest Management

Act of 1976 (16 U.S.C. 1600); and livestock stocking rate and forage utilization guides. These types of independent element limits are designed to protect or exploit a particular ecosystem element, but are not assessed in the context of other elements across a landscape platform.

A management strategy that emphasizes the production or conservation of a single element, without a landscape context, will likely disrupt the pattern and process of other elements. Many independent element limits are also disassociated from their ecological processes. For example, buffer distances for streams and riparian areas are commonly designed using distances that have little relation to the landform and soil conditions. When arbitrary limitations (for example, buffer widths) are implemented, they commonly fragment ecological processes. In the long term, the disequilibrium caused by disruption of landscape patterns and processes may very well cause the decline of the element that the independent limit was designed to protect (Allen and Hoekstra 1992).



Scenarios of Management

In our assessment of historical and projected future trends of landscape condition within the Basin, we strived to address two very different approaches of managing natural resources. We simulated and evaluated a "contextual opportunity and risk" paradigm, along with the "independent element limits" paradigm. The "active (ecological) management" scenario was designed to incorporate the contextual opportunity and risk model, whereas the traditional "consumptive demand" and "passive" scenarios were designed to address the model of independent element limits. Active management is designed to produce properly functioning landscape patterns, whereas consumptive demand produces traditional commodity landscape patterns, and passive management produces traditional reserve landscape patterns. Although it may at first appear odd that we considered the traditional commodity and reserve landscape patterns to both be produced from one conceptual model, we hypothesize that the long-term effects of each strategy are nearly the same.

OVERVIEW OF METHODS

Characterization of Multi-scale Landscape Relationships

These methods are an overview of the key analyses that were conducted to assess landscape dynamics. For more detail we refer the readers to Hann and others (1997), Hessburg and others (1996a), Ottmar and others (1996), and Keane and others (1996b).

The broad-scale data for this assessment were coarse grained (low resolution), but continuous across the Basin. Conversely, the mid- and fine-scale data were finer grained (higher resolution), but were sampled from the Basin and therefore not continuous. Using a multi-scale approach improved our understanding of the relationships among fine-, mid-, and broad-scale vegetation attributes.

Plot data (fine-scale) obtained from various agencies were inconsistent in type, methods, and data quality control. Data were relatively consistent within, but not among administrative units. The most consistent statistical correlation of the plot data was found within the administrative unit that collected the data. Very few attributes demonstrated adequate consistency of values and interrelated logical relationships to provide confidence in the use of plot data as a whole. Consequently, we only used a very reduced data set that had consistent and standard methodology, and that had been corrected for errors in logical relationships.

Although mid-scale vegetation inventory map data were available from various sources, such as satellite remote sensing and forest, rangeland, and wildlife habitat inventories, they were as variable and inconsistent as the plot data. Legends were difficult to correlate among different maps; even though map legend attributes were labeled identically among maps, the attributes themselves were often different. Furthermore, most of the vegetation maps did not have corresponding potential vegetation maps of the same scale, and major problems with logical relationships existed for those that were of the same scale. Consequently, we were unable to use existing mid-scale vegetation-inventory maps and were forced to develop a new set of mid-scale data that was consistent and rectified with a potential vegetation layer (see Hessburg and others 1996a). The mid-scale data set was derived from a two-stage, stratified random sample of paired "current" and "recent historical" aerial photography covering 337 subwatersheds from 43 subbasins. The areal coverage of the subsample was equivalent to approximately 5 percent of the Basin. Many of the recent historical data (1930-1960s), particularly on rangelands, were derived from relatively recent aerial photography. Conversely, some of the current aerial photography (also primarily on rangeland-dominated subwatersheds) was relatively old (1980-1990s).

Table 3.4—Total percentages by management region, land ownership group, and management class.

Management Region	Land Ownership Group, Management Class[1]	Percent of Management Region	Percent of Total Basin

[4]Upper Columbia River Basin EIS assessment area.

Consequently, the recent historical and current photographic pairs spanned various temporal periods [see Hessburg and others (1996a) for further details of the mid-scale sampling design].

The mid- and fine-scale data that were strongly correlated with broad-scale data could be extrapolated across the entire extent of the Basin. We observed several attributes that were correlated among the three scales when stratified by geographic area: land ownership, management strategy, and groups of potential vegetation groups (PVGs). We divided the Basin into two geographic areas or management regions: the Eastside (EEIS) and the Upper Columbia River Basin (UCRB). Land ownership and management strategies were stratified into eight management classes (table 3.4). Because our analysis focused on BLM- and FS-administered lands, we further aggregated the non-BLM- and FS-administered lands into a single "Other" lands category (map 3.7).

Map 3.7—Management classes for the Basin (EIS data). This version of the management classes was developed to incorporate roaded and non-roaded areas as an additional modifier to the management process.

Often, the relationships among the three different scales were complex and not immediately obvious. In order to correctly interpret the differences among scales, we often had to qualitatively or quantitatively develop a broad-scale correlate to assess trends of mid- and fine-scale conditions.

For example, although we could assess the broad-scale areal extent of fires, the mid- and fine-scale patterns of fuel types and fire behavior differed substantially. These differences were apparently due to the management history of an area — which was correlated with the management objectives of that area [for instance, managed as wilderness or roadless areas (wilderness-like), or managed primarily by human-influenced processes (non-wilderness or roaded areas)]. Consequently, mid- and fine-scale fire behavior attributes (that is, crown fire, fire severity, fire interval, and smoke) would not necessarily be the same for two areas having similar types of broad-scale fire and/or physiognomic vegetation conditions.

Broad-Scale Trends

The broad-scale variables used to assess regional levels of change included PVTs, PVGs, cover types, structural stages, physiognomic types, physiognomic type groups, terrestrial communities, disturbance types, roads, and strata of lands having similar ownership and management objectives (management class). These variables were assessed for historical and current period conditions and projected for future scenarios. Current conditions reflected a coarse, general depiction of the Basin circa 1990 (representative of the 1985-1995 decade). Historical conditions reflected a coarse, general depiction of how the Basin might have appeared circa 1850 to 1900, prior to major changes caused by Euro-American settlement. The "native" system refers to the regime prior to Euro-American settlement (that is, the historical range of variability). In some cases "historical" may be used in a generic sense to refer to HRV. The native regime, with respect to the HRV, was simulated. The broad-scale vegetation attributes of the current period were derived from 1991 satellite imagery. We formulated two sets of historical, current, and future projection data. The first set was summarized in 1995 as a preliminary assessment used by the Environmental Impact Statement (EIS) teams to formulate a preliminary set of land-management alternatives. A second set of more refined data was summarized in 1996 for the EIS teams. The processes of defining cover types, structural stages, and PVTs are described by Menakis and others (1996). The vegetation dynamics models are described by Byler and others (1996) and Long and others (1996). A detailed documentation of data analysis procedures was provided by Hann and others (1997). Regional and landscape modeling procedures were documented by Keane and others (1996b). Methods pertaining to the development of primary Geographic Information System (GIS) themes and input layers were described by Menakis and others (1996) and in Chapter 8, Information System Development and Documentation, of this document.

Cover types and structural stages were aggregated into terrestrial communities (appendix 3-B) to assess habitats, and into physiognomic types (appendix 3-C) to assess successional and disturbance processes. Although, the cover types and structural stages assigned to terrestrial communities remained the same between the 1995 and 1996 data sets, assignments to physiognomic types were modified in the 1996 version (see appendix 3-D). The 1995 version of physiognomic types did not incorporate shade-tolerant/shade-intolerant relationships for the forest types, but they were reported in a separate set of tables for the 1995 version. After the 1995 analysis, we incorporated the shade-tolerant/shade-intolerant assignments with the broad-scale physiognomic types. The 1995 version was reported by Hessburg and others (1995), because it was a key summary used by the EIS teams. In the 1996 version, we aggregated the physiognomic types into physiognomic type groups to reduce the number of stratifications. If given another opportunity to analyze the data, we would not have developed two independent groupings of cover types and structural stages (that is, terrestrial communities and physiognomic type groups).

Instead, we would use our final physiognomic type groups, stratified by PVG, for both the terrestrial habitat assessment and the evaluation of succession and disturbance processes.

Menakis and others (1996) compared the broad-scale classes of potential vegetation and current period vegetation, to mid-scale data presented in Hessburg and others (1996a)(table 3.5). The comparison applied to the current condition of the broad-scale PVTs and PVGs, cover types, life forms, structural stages and groups of structural stages, terrestrial communities, and physiognomic types and physiognomic type groups. These comparisons indicated that the broad-scale data was, for the most part, less than 40 percent comparable to the mid-scale data on a cell-to-cell basis. Consequently, we had moderate confidence in cell-to-cell comparisons except for types with large amounts that occur in uniform patches. However, the comparability was substantially improved when the broad-scale data were summarized by relatively large geographic areas. For example, the mid- and broad-scale cover types, structural stages, PVTs, and physiognomic types had an average comparability of 48, 58, and 76 percent at the subwatershed, subbasin, and Basin levels, respectively. For groups or types with large amounts this increased at each scale by 10 to 30 percent. Thus, increasing the size of the geographic area at which the data was summarized, grouping types, and focusing on dominant types increased the comparability of our mid- and broad-scale data.

Of the vegetation attributes tested, structural stages were the most difficult to map with high comparability between the two scales. Aggregation of vegetation attributes into coarser classes (for example, from physiognomic types to physiognomic type groups, or from PVTs to PVGs) or focusing on dominant types or groups also improved the comparability of mid- and broad-scale data. Consequently, we restricted the majority of our analyses of broad-scale landscape dynamics to areal trends of coarse classes or dominant types that were summarized for relatively large geographic areas (such as, subbasins, clusters of subbasins, ERUs, and the Basin).

Biophysical Template

The PVGs (appendix 3-A) were used as indicators of broad-scale biophysical templates. We assessed the historical and current areal extent of each of the PVGs in relation to its general environment, land ownership pattern, composition of physiognomic types, and predominant disturbance regimes. Each of the PVGs was stratified at 1,200 meters mean sea level (MSL) to assess trends above and below that elevational breakpoint. In addition, we used a composite assessment to index the departure of the current PVG from its historical succession and disturbance regimes into three classes: low, moderate, and high.

Data for the assessment of PVGs were then derived from simulations of the historical and current periods using the Vegetation Dynamics Development Tool model (VDDT) (Beukema and Kurz 1995), the Columbia River Basin Succession Model (CRBSUM) (Keane and others 1996b), ecological vegetation and site plot data (Hann and others 1997), and historical vegetation mapping with comparison to current photo points (Losensky 1994, Losensky 1995). The dynamics of the historical physiognomic types were simulated using a single 100-year run of the CRBSUM (Keane and others 1996b). We believed that a 100-year simulation of the historical dynamics captured the majority of the shifts in cover types and structural stages, and the associated succession and disturbance processes that would have occurred prior to Euro-American settlement and industrialization of the Basin. However, through sensitivity testing with the VDDT models we found that a 300-year period was generally required to produce consistent pattern repetitions (Hann and others 1997). Consequently, we conducted an additional CRBSUM historical simulation for 400 years.

Table 3.5—Comparison of broad-scale and mid-scale current vegetation and potential vegetation classes.

		Cell-to-Cell Overlay Comparison			Area Composition Comparison Percent Agreement[1]

Succession and Disturbance Processes

Vegetation structure and composition changed as a result of the interaction between disturbances and the subsequent successional responses that occurred. These processes changed the live and dead attributes of vegetation composition and structure, and the associated site conditions such as soil cover and soil organic matter.

We used the PVTs and the PVGs (appendix 3-A) to stratify the succession/disturbance regimes by biophysical environment. The PVTs were named for the dominant vegetation that could potentially grow on a site in the absence of disturbance, and were grouped into PVGs based on similar moisture and temperature gradients (Menakis and others 1996). Succession and disturbance processes were described and modeled for each PVT within the Basin (Beukema and Kurz 1995, Byler and others 1996, Hann and others 1997, Keane and others 1996b, Long and others 1996). A VDDT model (Beukema and Kurz 1995) was developed for each PVT to simulate cover type and structural stage changes that were attributable to the predominant disturbances of the historical, current, and future scenarios through time (Byler and others 1996, Keane and others 1996b, Long and others 1996). The VDDT models and Losensky's (1994) historical vegetation information suggested that year 0 of the historical simulation represented a generalized historical condition of cover type and structural stage dynamics. Modeling suggested that the PVTs in the Basin generally required 250 to 400 years to cycle and stabilize at a relatively constant composition of vegetation cover types and structural stages. These models were also used to assess trends of regional and landscape composition and structure.

Our evaluation included what we believed were the primary disturbance regimes. The evaluation took into account fire severity and fire interval (Morgan and others 1996), recent fire occurrence (Menakis and others 1996), roads (Menakis and others 1996), grazing (Burkhardt 1996), climate (Ferguson 1996a, 1996b, 1996c, 1996d), and human activities (Woods and Horstman 1996). In addition, we considered the paleoecological influences reported by Mehringer (1996). The simulations incorporated succession rates and disturbance effects in the modeling of regional and landscape composition and structure changes. Results of historical, current, and future modeling of different types of management were summarized by Keane and others (1996b) and Long and others (1996). Keane (1996) reported the results of modeling ecosystem processes. Response coefficients for modeling fire behavior and effects were adopted from Hardy and others (1996). Results of modeling the different effects of smoke from wildfire and prescribed fire were summarized by Holsapple and Snell (1996). Schoettle and others (1996) summarized the dynamics of air quality.

We developed a classification that separated succession/disturbance regimes into (1) regimes that generally maintained communities and (2) regimes that cycled communities through successional stages (table 3.6). Within these two classes, we provided for subdivisions based on the interval between disturbance, types of structures created by the disturbance, and the associated disturbance severity. Because the classification system was based upon succession and disturbance processes, it allowed us to readily predict succession and disturbance patterns without having detailed information on the causal disturbance agents (for example fire, drought, insect and disease infestation, stress, or wind). These regimes were developed from interpretations of plot data and historical photo points (Hann and others 1997; Losensky 1995) along with reference to the current succession and disturbance literature discussed in the introduction to this chapter.

Morgan and others (1996) mapped fire regimes that were based primarily upon frequency (the interval between successive fires) and severity (the fires' effects on the dominant overstory vegetation). They used two sets of decision rules (one set for historical regimes and another set for the current period regimes) to assign fire regime classes to cover types. Assignments were based upon published literature, a fire history database (Barret 1995), and expert opinion.

Table 3.6—Succession and disturbance regimes developed for broad-scale assessment.

Regime (Code)	Average Disturbance Interval (years)		Severity	Description	Examples
	Intermediate Mixed[1] / Non-lethal[2]	Lethal			
Cycling	NA[3]	1+	Moderate-High	Succession is reinitiated by disturbances that are lethal[4] to most or all of the upper-layer and some or all of the lower-layer vegetation.	
Accelerated Cycle (AC)	5 - 50	30 - 300	Moderate	Intermediate disturbances that accelerate growth of disturbance-adapted species, often creating an irregular fine-scale mosaic of patches of different vegetation structures. Eventually cycled by a lethal disturbance.	Conifer potential vegetation types (PVTs) with non-lethal or mixed fires, insect, or disease effects that thin the stands of susceptible species, allowing the resistant species to accelerate growth; shrub PVTs with non-lethal or mixed fires, insects, disease, grazing, or beaver cutting effects that open-up stands.
Long Cycle (LC)	NA	101 - 300	High	Successional cycle is long, with reinitiation from seedlings and some resprouting. Intermediate disturbances may happen but they have minimal effects on composition, structure, and density.	Conifer PVTs with longer-lived, fast-growing, shade-intolerant, conifer species that dominate after crown fires, insect attacks, windthrow, or other lethal effects that cycle the community.
Moderate Cycle (MC)	NA	5 - 100	Moderate	Successional cycle is moderately long, with reinitiation from a mixture of resprouting plants and seedlings. Intermediate disturbances may happen but they have minimal effects on composition, structure, and density.	Shrub PVTs where succession after lethal burning, herbicide application, chaining, or insect topkill takes from 10 to 25 years to reestablish the dominant shrub layer; conifer or broadleaf PVTs with short-lived, fast-growing, shade-intolerant, conifer or broadleaf species that dominate after crown fires, insect attacks, windthrow, or other lethal effects that cycle the community; floods in floodplain areas that cycle broadleaf, conifer, or shrub vegetation; cutting or flooding by beaver in riparian areas; avalanche paths; conifer PVTs where lethal disturbance cycles the vegetation prior to dominance by conifers, keeping the system in an herb or shrub dominated stage.
Retrogressive Cycle (RC)	NA	10 - 50	Low	Disturbances that reverse successional direction to an earlier seral stage, typically an annual or biannual cycle of grazing stress insect/pathogen mortality, drought mortality, or pollutant mortality.	Conifer PVTs with fire exclusion resulting in a dense upper layer that undergoes relatively little annual mortality from insects, disease, and stress that cumulatively are a lethal effect to the dominant vegetation over a long period (10-50 yrs); grazing that selectively causes mortality in relatively small annual increments such that over a long period there is a complete change in dominant vegetation composition or structure; invasion by exotic plants that can compete more effectively than native plants due to environment or disturbance (grazing, fire, tillage, or roads).

Table 3.6 (Continued).

Short Cycle (SC)	NA	1 - 4	High	Successional cycle is very short with a composition of new seedlings, annuals, biennials, or weedy perennial species.	Annual high water in channel zone/draw area adjacent to the channel; annual tillage in agriculture; soil or gravel surfaced roads with annual grading and runoff; annual grass and weed dominated vegetation with high amounts of bare soil; annual avalanche path areas.
Very Long Cycle (VC)	NA	301+	High	Successional cycle is very long, with reinitiation primarily from seedlings. Intermediate disturbances may happen but they have minimal effects on composition, structure, and density.	Conifer PVTs with a sequence of dominance by shade-intolerant tree species that succeed to shade-tolerant tree species and then are cycled by crown fires, insect attacks, windthrow, or other lethal effects on the dominant upper layer vegetation.
Maintenance	5 - 50	NA	Low	Succession is maintained in one structural stage by periodic disturbances that do not cycle the upper-layer vegetation but are lethal to species in the lower layer that would grow up into and change the upper layer.	
Frequent Maintenance (FM)	5 - 25	NA	Low	Intermediate effects produce relatively uniform upper and lower layers of vegetation with relatively short intervals between maintenance disturbances.	Warm conifer PVTs with non-lethal fires, insects, disease, or grazing effects that selectively remove the susceptible understory species allowing for recruitment of resistant species into the overstory; warm grassland, shrubland, and conifer PVTs with non-lethal and mixed fires, insects, disease, or grazing effects that maintain the dominant grass or forb vegetation.
Less Frequent Maintenance (GM)	26 - 50	NA	Low	Intermediate effects produce relatively uniform upper and lower layers of vegetation with moderate intervals between disturbances.	Cooler conifer PVTs with non-lethal fires, insects, disease, or grazing effects that selectively remove the susceptible understory species allowing for recruitment of resistant species into the overstory; cooler grassland, shrubland, and conifer PVTs with non-lethal and mixed fires, insects, disease, or grazing effects that maintain the dominant grass or forb vegetation.
Irregular Maintenance (IM)	26 - 50	NA	Low	Intermediate effects produce relatively irregular upper layers of vegetation and multiple lower layers.	Wet conifer, broadleaf, or shrub PVTs with mixed fires, insects, disease, or grazing effects that selectively remove small patches of susceptible species in any vegetative layer allowing for recruitment of resistant species into the structure.

[1]Mixed disturbances maintain a salt and pepper, fine-scale mosaic within a patch by cycling clumps and gaps; mixed disturbances leave patches intact, but maintain a rough textural pattern of clumps and gaps; mixed disturbances can be lethal (maintaining scattered gaps or creating gaps); or non-lethal (creating gaps that are intermingled with clumps).

[2]Non-lethal disturbances do not cycle the upper layer of vegetation; non-lethal disturbances selectively thin susceptible plants in all layers of the patch.

[3]NA = Not Applicable.

[4]Lethal disturbances cycle the upper layer of vegetation in the patch, and may cycle the lower layers.

The decision rules for the current regimes reflected the influence of fire suppression, invasion of exotic plants, and other human-caused factors. Neither of the rule sets used vegetation structure nor fuels for modeling potential fire behavior. Consequently, we had less confidence in the current fire-regime map and associated regime change maps, than in the historical fire regime map. However, we believe that the indices of historical and current fire regime classes could be confidently used to assess broad-scale trends. In addition, if used in conjunction with other proxy variables, we believe that the fire regime classes could also be used to estimate potential fire risk and fire behavior.

We used five indices to estimate regional risks of severe fire behavior and severe fire effects. The five indices were based on the proportion of an ERU that had: (1) mixed or lethal historical fire severity; (2) an increase of fire severity or decrease of fire frequency (that is, an increase of infrequent and very infrequent classes) between historical and current periods; (3) a high probability of fire occurrence; (4) a high probability of severe fire behavior; and (5) the presence of rural/wildland interface. Fire-occurrence probabilities were based on seven years (1986-1992) of subwatershed fire-occurrence records. The fire behavior index incorporated elevation, precipitation, and temperature gradients. The overall index of severe fire risk was calculated as the average value of the five indices described above (see Hann and others 1997, Long and others 1996, and Menakis and others 1996 for a more detailed description of methodologies).

We also developed indexes for precipitation, seasonal climate gradients, and topoedaphic conditions to use in assessing succession and disturbance processes (Hann and others 1997). Coefficients were calculated for rule sets to estimate amounts of net wildfire, wildfire suppression cost, forest crown wildfire, forest surface/mixed wildfire, forest insect/disease, smoke, and soil disturbance. Subbasin landforms were developed by identifying the dominant subsection landforms for each subbasin.

Road density classes were mapped from a rule set using categories of land ownership, land use, life form, elevation, slope, and a GIS road data set obtained from United Parcel Service (Menakis and others 1996). The density classes and relationships to the categories were extrapolated from mid-scale subwatershed road data. Although we were not able to test the extrapolation rule set, or conduct a comparison analysis between the final broad-scale road density map and the sampled subwatersheds, we were able to evaluate the logic of the road density classes and refine the rule sets. Although we do not have a high degree of confidence in the absolute values of the broad-scale road density classes, we do believe that they can be appropriately used to assess broad-scale trends of relatively large geographic areas (for example, clusters of subbasins, basins, and ERUs).

The mid-scale subwatershed road data, photo points, and reconnaissance notes were used to develop interpretations of fine-scale effects of roads (Hann and others 1997).

Biogeochemical Processes

Biogeochemical processes were simulated using a mechanistic biogeochemical model (BGC) to improve our understanding of the fundamental processes responsible for vegetation dynamics, and to provide a coarse summary of the productivity and ecophysiological vigor of historical, current, and projected future vegetation under several climatic conditions. The routing of key elements through the critical subsystems of the terrestrial ecosystem was simulated. We believed that the assessment of productivity and the flows of water, carbon, and nutrients through the ecosystem would provide important insights for evaluating landscape relationships.

The BGC model used daily and annual timesteps to simulate the flows of carbon, nitrogen, and water through an ecosystem. The BGC model incorporated the critical subsystems through which carbon, nitrogen, and water must flow,

including the atmosphere, soil, and the roots, stems, and leaves of plants. The model simulated the flow of carbon, nitrogen, and water across these subsystems using physiological process relationships. For example, carbon is transferred from the air to the leaves, stems, and roots via photosynthesis. The carbon lost from leaves, stems, and roots is transferred to the soil and air via litterfall and decomposition. The driving variables used to simulate the physiological relationships included precipitation, temperature, and radiation. Atmospheric carbon is fixed by photosynthetic plants. The rates of photosynthesis, and consequently carbon fixation, are dependent upon available solar energy, temperature, water, and humidity. Carbon is released back into the atmosphere from autotrophic (green plants) and heterotrophic (microbial) respiration processes that are primarily dependent on temperature. Water is absorbed by plants through the roots depending on the soil-water potential and then released into the atmosphere via transpiration. The rate of transpiration is mostly governed by humidity, temperature, and available soil moisture.

The BGC model was developed as an improvement on previous models for single-tree, single-year, daily water balance (H_2OTRANS), and community level processes (Running and Coughlan 1988, Running and Gower 1991). The current version of the BGC model simulated processes across all biomes, including human-altered vegetation such as agricultural and exotic-dominated forblands. Biogeochemical processes were simulated at a 4-square-kilometer resolution because the weather data were only available at that scale. A detailed discussion of the BGC model and its application to the landscape ecology assessment of the Basin is contained in Keane and others (1996b) and Thornton and others (in press).

The current and historical cover type and structural stage maps were used to develop the input layers required by the BGC model. The current data layers described conditions as they occurred circa 1990 (representation of the 1985-1995 decade), while the historical layers described conditions as they occurred around the turn of the century (circa 1850-1900). The number of potential-output variables was limited to gross photosynthesis, maintenance respiration for each carbon subsystem, evaporation, transpiration, and the coefficients controlling soil and litter decomposition. Summary maps were generated in which the grid cells were attributed by the sum of each variable, for the historical, current, and future management scenario maps. The summary maps were used to generate several spatial data layers that projected ecosystem processes in the Basin. Four indices developed by Thornton and White (1996) were selected to assess physiological processes: (1) net primary productivity, (2) carbon stress, (3) water stress, and (4) nutrient availability.

Net primary productivity index

Simply stated, the net primary productivity (NPP) index is an indicator of the growth potential of vegetation within an ecosystem. Net primary productivity was simulated from the annual summaries of gross photosynthesis (GPSN) and maintenance respiration for all carbon subsystems ($\sum$MR). Net primary productivity was estimated as:

$$NPP = GPSN - \sum MR$$

An estimate of growth respiration was not deducted from NPP. Consequently, the estimate of NPP should be reduced by 20 to 40 percent in order for it to be comparable to field estimates.

Carbon stress index

The carbon stress index (CSI) was used to approximate the influence of respiration costs on the production potential of the vegetation. The CSI was estimated from the ratio of maintenance respiration to gross photosynthesis and consequently described the balance between annual gross productivity and maintenance costs. CSI was estimated as:

$$CSI = \sum MR / GPSN$$

CSI values close to 1.0 indicated that most of the annual production of photosynthate was consumed by respiration costs attributable to the maintenance of living tissue. Values near zero suggested that a large surplus of the annual photosynthate production was available for new growth, production of protective compounds, or reproduction.

The CSI functioned as an indicator of ecophysiological health and the vegetation's relative susceptibility to stress, or disease, and insect attack. It was more diagnostic in these respects than NPP, because it placed vegetation types having different productive potentials on the same scale. This allowed for the comparison of relative vigor or, alternatively, their susceptibility to insects and disease. For example, in the comparison of a late-seral forest type with an early-seral forest type, NPP estimates might be higher for the late-seral forest than for the early-seral forest; there is, therefore the potential interpretation that the older forest is more vigorous or less susceptible to disease or drought. Depending on the amount of living tissue being supported in each of these communities, the CSI might reveal that the older forest used 80 percent of its annual photosynthate production in maintenance costs, while the early-seral forest used only 40 percent, thus providing an alternative interpretation of the relative health of the two communities. CSI values of greater than 0.8 indicated high carbon stress and poor ecosystem health. CSI values of 0.6 to 0.8 indicated moderate stress, and values less than 0.6 indicated healthy, unstressed ecosystems. Strong carbon balance (that is, CSI < 0.6) had sufficient carbon available for growth, reproduction, and defensive chemistry. Weak carbon balances had less energy allocated to the carbon sinks.

Some values of CSI exceeded 1.0, which suggested that the annual maintenance respiration costs exceeded the gross production of photosynthate. In the short term, perennial vegetation types capable of using stored carbon are able to tolerate carbon deficits. For example, a mature forest may be able to withstand a particularly dry year or an insect defoliation event resulting in a net loss of photosynthate by using carbohydrate reserves stored in stem and root tissues. However, during these periods, the carbon reserves are reduced and mortality may result if production is low, or respiration costs are high in successive years. Annual plants or seedlings of perennials do not have adequate reserves, and would likely succumb to these conditions in a single year. Since the vegetation types and structural stages used in the simulations were determined externally in the model and no mechanistic feedbacks existed between vegetation types, potential mismatches between site conditions and vegetation type or structural stage could occur. Consequently, CSI values exceeding 1.0 were possible. Similarly, the spatial and temporal variability of meteorological conditions and vegetation communities could result in exceedingly high values for the CSI.

Water stress index

Water availability is a key limiting factor for the vegetation throughout a large proportion of the Basin. The water stress index (WSI), estimated as the ratio of total annual evapotranspiration (ET) to total annual precipitation (PPT), was an indicator of water availability.

$$WSI = ET / PPT$$

Values approaching 1.0 were generally indicative of arid conditions, where low soil moisture likely limited production. Values close to 1.0 may also have occurred in areas having substantial precipitation, but where the evaporative demand was high. Consequently, vegetation having relatively high leaf areas could be susceptible to water stress in such regions. Low WSI values (< 0.65) were indicative of a water surplus, which under annual soil water equilibrium conditions, was manifested as hydrologic outflow. Sites with low WSI values typically occurred in areas having abundant winter precipitation, such as subalpine and alpine areas. However, low values could also occur in sparsely vegetated sites and at lower elevations, where precipitation exceeded bare soil evaporation.

Moderate WSI values of 0.65 to 0.85 suggested that water could be limiting to plant growth during some part of the growing season. High values (> 0.85) indicated water could be limiting to plant growth and most precipitation was probably used by the vegetation or lost through evaporation, and there was little to no hydrologic outflow or groundwater recharge.

Nutrient Availability Index

Many of the components required for a thorough assessment of broad-scale nutrient availability could not be adequately estimated. Although the analysis of the current period lacked many of the components required for a realistic estimation of nutrient availability, a few of the most relevant factors were summarized into the nutrient availability index (NAI). In this analysis, the term "nutrient" applied principally to nitrogen, although some of the following findings were applicable to other nutrients as well.

The decomposition of organic matter in the litter and soil is the principal nutrient source for vegetation that lacks the ability to fix atmospheric nitrogen. We estimated a composite decomposition coefficient that integrated the effects of soil moisture and temperature on the relative decomposition rate. Litter organic matter is the most important pool acted upon by the decomposition coefficient because it has a high nitrogen-to-carbon ratio (N:C), which provides a good substrate for heterotrophs that decompose organic matter. The soil organic-carbon pool, although typically many times larger than the litter organic-carbon pool, is of a poorer quality (lower N:C), decomposes more slowly, and is consequently, less important to plants. Our best indicator of the litter organic pool was the estimate of NPP. However, this assumed that on an annual basis all the organic matter resulting from NPP would be returned to the litter, either as leaf, stem, or root turnover. This is not entirely accurate, since conditions of net growth and net decline of live biomass are common. Nevertheless, it was likely that these components (growth and decline) would be most closely correlated with NPP. Thus, as a relative scalar of potential decomposition, NPP seemed to be a logical choice.

The NAI was derived by multiplying the annual average decomposition scalar (d_s) by the annual NPP, and was therefore comparable across vegetation types.

$$NAI = (d_s)\ NPP$$

The NAI was a crude approximation of the potential nutrient availability based on the rate of decomposition and productivity. The decomposition scalar was a function of daily soil temperature and soil water content summed over the year (Running and Hunt 1993). High values were associated with wet, warm soils and low values were indicative of cold and/or dry soils. The decomposition coefficient represented the potential rate of decomposition, whereas the actual rate of decomposition was dependent on the supply of litter and other organic material on the ground. A reasonably good representation of the potential organic material supply could be portrayed by NPP, since NPP is directly proportional to litter production. The product of NPP and the decomposition coefficient account for the amount of decomposition for a given year. The relationship between NAI and nutrient availability is a function of litter quality or lignin content. No attempt was made to integrate lignin interactions into NAI. Low NAI values (< 0.05) signified low decomposition rates and high amounts of nutrients tied up on the ground and in plant parts. High values (> 0.25) indicated rapid decomposition rates, highly-productive environments, and more nutrients available for plant growth.

Broad-scale Changes in Cover Types

Forty-one broad-scale cover types were mapped at 1-square-kilometer resolution to describe the current and historical period vegetation of the Basin (appendix 3-E). Cover types were named for the vascular plant species having the dominant canopy cover for rangeland types (Shiflet 1994) and the dominant basal area for forest types (Eyre

1980). The current cover type map was created by Hardy and others (1996) by refining a land cover characterization map that was constructed from a 1991 classification of Advanced Very High Resolution Radiometer (AVHRR) satellite imagery (Loveland and Ohlen 1993, Loveland and others 1991). This map was revised using rule sets developed from knowledge of the PVT, a rectification procedure using CRBSUM, and information gained from workshops attended by ecologists familiar with the Basin (Keane and others 1996b, Hann and others 1997; Menakis and others 1996). The historical cover type map was produced by Losensky (1994) using archived maps and government records published near the turn of the century and revised using a rectification process similar to that for the current. Because the base historical map was compiled from many maps of varying scales and quality, it was difficult to cross-reference historical and current cover types. This was especially true for urban and agricultural areas. The derivation of current and historical vegetation layers and rectification with current and historical PVT layers was fully described by Menakis and others (1996) and Hann and others (1997).

Two spatial scales and three indices of change were used in this assessment to quantify areal changes of cover types between historical and current periods. Compositional changes were assessed across the Basin as a whole, as well as within the 13 ERUs (map 3.3) within the Basin. These changes were evaluated with respect to the cover type (that is, class change), to a region (that is, Basin or ERU change), and to the historical range of each cover type (that is, departure index).

Class changes quantified the proportional change of a cover type's area between the historical and current periods. Class change was estimated by:

$$CC = [(CTA_C - CTA_H)/ CTA_H] * 100,$$

where

CC = percentage of class changed,

CTA_C = current area of cover type, and

CTA_H = historical area of cover type.

Regional changes quantified the areal proportion of the region (Basin or ERU) that was altered as a result of the change in areal extent of a cover type. Regional change was estimated by:

$$RC = [(CTA_C - CTA_H) / RA] * 100,$$

where

RC = percentage of region changed,

CTA_C = current area of cover type,

CTA_H = historical area of cover type, and

RA = regional area (Basin or ERU).

Transition matrices of cover types were constructed to further our understanding of class and regional changes (Jones 1996). The transition matrices tracked the flux of individual 1-square-kilometer pixels from one cover type to another between the historical and current periods. For example, did a pixel that was classified as a ponderosa pine cover type during the historical period remain ponderosa pine, or did it change to another cover type in the current period? The dominant transitions within a region (that is, those affecting at least 1% of the Basin or an ERU) were summarized.

Cover type departure indices were determined by comparing the current period areal extent of each type to their modeled median 75-percent and 100-percent historical ranges. The median 75-percent range is 75 percent of the difference between minimum and maximum, which excludes 12.5 percent of the range from each end. We computed the median 75-percent range to exclude some of the more extreme variation. Historical ranges of cover types were simulated for the Basin and individual ERUs using the CRBSUM (Keane and others 1996b). The minimum and maximum values from a single 100-year or 400-year run of the CRBSUM, and appropriate outputs for simulation years 0, 50, 100, 200, 300, or 400 were used to define historical ranges. The initial conditions for the historical simulations and the simulation process were described by Menakis and others (1996) and Long and others (1996), respectively. We then calculated the median 75-percent historical range by adding or subtracting 12.5 percent of the

Table 3.7—Cover type and terrestrial community departure classes.

Departure Class	Relationship of Current Period Area to Historical Ranges
1	A_c[1] < Historical Minimum
2	Historical Minimum ≤ A_c < Median 75% Historical Range
3	A_c is within Median 75% Historical Range
4	Median 75% Historical Range < A_c ≤ Historical Maximum
5	A_c > Historical Maximum

[1]A_c = Current area.

historical range to the historical minimum and historical maximum, respectively. Five departure classes were defined based on the relationship between the current area of each cover type and its simulated median 75-percent and 100-percent historical ranges (table 3.7; fig. 3.10).

We used class changes, regional changes, and departure indices to determine ecologically significant changes of cover types. We judged the absolute value of class changes greater than or equal to 20 percent and regional changes greater than or equal to 1 percent as ecologically significant, but only if the departure indices indicated that the current area of the cover type occurred outside its median 75-percent historical range (that is, departure classes 1, 2, 4, and 5). In turn, areal changes resulting in departures classes 1, 2, 4, and 5, were ecologically significant if either the historical or current period areas of a cover type exceeded 1 percent of the region, and the class change exceeded 5 percent.

The herbaceous wetlands, shrub wetlands, and aspen cover types appeared to be under-represented in the historical vegetation layer and over-represented in the current layer. These types, which generally occur in scattered, relatively small- to medium-sized patches, tend to be underestimated as mapping resolution increases (Turner and others 1989). Because the historical vegetation layer was developed at a coarser resolution than the current period vegetation layer (Menakis and others 1996), it was likely that the two mapping efforts contained different biases. In fact, rectification with the PVTs indicated that the herbaceous wetlands, shrub wetlands, and aspen cover types were likely more abundant on the historical landscape than the data indicated [see appendix 3-F for a description of PVTs, and Menakis and others (1996) for the derivation of the historical vegetation layer]. Changes in these three types were not reported because they could not be accurately quantified.

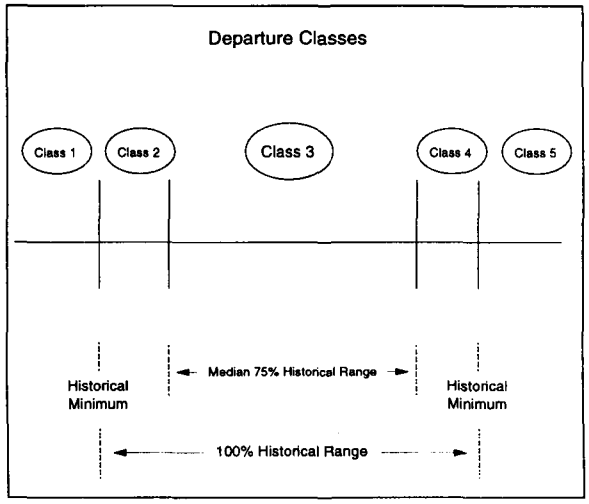

Figure 3.10—Relationship between current areal extent of cover types and terrestrial community types, and their respective median historical ranges.

Broad-scale Changes in Terrestrial Community Types

Twenty-four broad-scale terrestrial community types were derived by aggregating 41 cover types and 25 structural stages (appendices 3-B and 3-G). Structural stages represented the developmental changes in a plant community's structure (Oliver and Larson 1990). Oliver's (1981) original forest structural stages were modified by O'Hara and others (1996) to account for the influence of natural and anthropogenic disturbances on successional development in forest and woodland types. Willard and Villnow (1996) developed a set of structural stages for rangelands that were later revised for use in a coarse-scale application. The current period structural stage map was created from a discriminant analysis of mid-scale data layers extrapolated to the broad scale (Keane and others 1996b). Data of historical structural stages were generated from historical information compiled by Losensky (1994), in which the areal extent of structural stages was summarized by cover type and county, and then extrapolated to Bailey's (1995) ecological section. Historical structural stages were then randomly assigned to pixels based upon the historical cover type and proportional area of structural stage within an ecological section (Keane and others 1996b). Cover types and structural stages were aggregated into terrestrial community types based upon moisture, temperature, elevational gradients, and similar broad-scale structures. Terrestrial community types were mapped at 1-square-kilometer resolution.

As with the analysis of cover types, two spatial scales and three indices of change were used to quantify areal changes of terrestrial communities between historical and current periods. Compositional changes were assessed across the Basin as a whole, and for ERUs within the Basin (map 3.3). These changes were evaluated with respect to the terrestrial community (that is, class change), the region (that is, Basin or ERU), and the historical range of a community's area (that is, departure index).

Class changes quantified the proportion of a terrestrial community's area that varied between historical and current periods, whereas regional changes quantified the areal proportion of the region (Basin or ERU) that was altered as a result of a change in areal extent of a terrestrial community type. The class and regional changes of terrestrial communities were estimated in the same manner as they were for cover types. Transition matrices of terrestrial communities were constructed to further our understanding of class and regional changes (Jones 1996). The dominant transitions within a region (that is, those affecting at least 1% of the Basin or an ERU) were summarized.

As with the cover type departures, terrestrial community type departures were determined by comparing the current period areal extent of each type to their modeled median 75-percent and 100-percent historical ranges. Ecologically significant changes between historical and current period terrestrial communities were determined in the same manner used for cover types.

The same problem was experienced with riparian terrestrial community types as was experienced with riparian cover types. Consequently, the changes of riparian terrestrial communities were not reported because they could not be accurately quantified.

Broad-scale Changes of Physiognomic Types

Cover types and structural stages were aggregated into 20 physiognomic types to assess successional and disturbance processes (appendix 3-C). The physiognomic types corresponded to the terrestrial community types in non-forest (that is, rangeland) settings. However, in forest settings the physiognomic types incorporated shade tolerance/shade intolerance, in addition to structural and seral status. The aggregation of cover types to infer shade-tolerant and shade-intolerant groups should be used cautiously, particularly with model projections of HRVs. Although we believe the data for

mid- and late-seral stages to be fairly reliable, the values for early-seral stages are questionable. Broad-scale physiognomic types cannot be directly associated with forest age, such as regeneration, young, mature, or old. However, we believe physiognomic types can be associated with forest age classes if they are stratified by PVG and disturbance history.

Regional trends of physiognomic types were stratified by PVG and land ownership, and assessed for the Basin and each of the 13 ERUs. In addition, the current areal extent of physiognomic types was compared to the HRV for each strata. The HRV was based upon the historical extent, and a single 100-year run of CRBSUM (using historical disturbance regimes) with outputs at 50 and 100 years. Consequently, three values (historical year 0, historical year 50, and historical year 100) were used to estimate historical minimum and maximum values.

Broad-scale Subbasin Vegetation Departures

Terrestrial community type departures were developed to estimate the magnitude of broad-scale habitat changes in forest and rangeland habitats within subbasins. One-square-kilometer resolution, continuous, broad-scale data summarized by subbasin (map 3.6) was used to assess habitat departures of forest and rangeland ecosystems. After aggregating 41 cover types and 21 structural stages into 24 terrestrial community types, the forest terrestrial community types having late-seral single-layered and late-seral multi-layered structures were further collapsed into a "late" class. Departure classes (table 3.7) were then estimated by subbasin for nine forest terrestrial community types and three non-forest (that is, rangeland) community types. We estimated current period departures for those terrestrial community types that composed at least 1 percent of the area of a subbasin for any output period of the historical CRBSUM run, or for the current period condition. Departure values were not determined for anthropogenic community types (that is, cropland, exotic, and urban), nor community types that remained relatively stable between historical and current periods (that is, alpine, rock/barren, and water community types). Departures were also not estimated for riparian community types because historical occurrence of riparian cover types was typically underestimated and current period occurrence was typically overestimated (Jones and Hann 1996b).

Subbasin departure classes were estimated in a similar manner as were the Basin and ERU departures of cover types and terrestrial communities. However, in the subbasin, the departures were determined on an individual subbasin level. Consequently, the current areal extent of each type within individual subbasins was compared to the modeled median 75-percent and 100-percent historical ranges of each type within a subbasin. Subbasin historical ranges of terrestrial communities were determined for the Basin and ERUs in the same manner as the historical ranges of cover types and terrestrial communities.

The persistence of species within a subbasin was presumed not to be at risk if the current period area of the species' primary habitat fell within or above the median range of historical data. Consequently, we believed it would be informative to assess the fragmentation of areas in which the risks to persistence would be relatively low. We computed four fragmentation indices for subbasins in which a community type occurred within or above its historical range: (1) percent area (percentage of those subbasins in which a community composed a substantial proportion); (2) number of patches; (3) median patch size (count of subbasins within a patch); and (4) maximum patch size.

Broad-scale Changes of Vegetation Patterns

We evaluated the patterns of physiognomic groups and terrestrial communities to assess landscape and regional patterns of vegetation, respectively, within the Basin.

Physiognomic Group Patterns

Physiognomic groups were derived from an aggregation of 41 cover types and 25 structural stages having similar gross compositional and structural characteristics (table 3.8). Physiognomic group patterns were in turn created by classifying subwatersheds (6th field HUCs) (map 3.5) according to their pattern and composition of dominant physiognomic groups. In the coarsest sense, patterns were simplified as "uniform", "mosaic", or "mixed". Uniform patterns existed where the dominant physiognomic group constituted a minimum of 80 percent of the subwatershed. The pattern was classified as mosaic where the dominant physiognomic group composed 60 to 80 percent of the subwatershed. In a mixed pattern, the dominant physiognomic group composed less than 60 percent of the subwatershed. A more descriptive pattern classification was also developed that used a hierarchy of pattern and dominant/codominant physiognomic groups. Changes of physiognomic group patterns were summarized by ERUs (map 3.3).

Transition matrices were prepared for each ERU to summarize the changes of physiognomic group patterns between the historical and current periods. Changes were quantified in relation to the physiognomic group (that is, class change or proportional change) and in relation to the ERU (that is, the proportional change of an ERU due to

Table 3.8—Physiognomic groups used to assess coarse landscape patterns of subwatersheds within the Basin.

Physiognomic Group	Description
Agriculture	Agricultural types including irrigated and non-irrigated crop land, hayland, and seeded pasture.
Forest / Woodland Early-seral	Forest and woodland early-seral structures (that is, stand initiation[1]).
Forest / Woodland Mid-seral	Forest and woodland mid-seral structures including stem exclusion open and closed, understory reinitiation, and young multi-storied stands.
Forest / Woodland Late-seral Multi-layer	Forest and woodland late-seral multi-layered stand structures.
Forest / Woodland Late-seral Single-layer	Forest and woodland late-seral single-layered stand structures.
Herbland	Herbland structures including both native and exotic grasses and forbs, and sedge-dominated open and closed stands.
Low Shrub	Low shrub structures including open and closed shrub stands less than 0.76 meters in height.
Mid Shrub	Mid shrub structures including open and closed shrub stands 0.76 to 2.00 meters in height.
Rock	Rock and barren structures.
Tall Shrub	Tall shrub structures including both open and closed shrub stands exceeding 2 meters in height.
Urban	Urban and industrial areas.
Water	Large bodies of water.

[1]See appendix 3-G for structural stages descriptions.

a change in a particular physiognomic group). The most dominant transitions within an ERU were evaluated to develop an understanding of the major pattern changes that had occurred between historical and current periods. In general, to be considered major, fluxes had to occur across a minimum of 1 percent of an ERU.

A coarse assessment of fragmentation trends was conducted by analyzing the net change in areal extent of ERUs that had fluxed between more uniform or more fragmented landscapes (that is, uniform to mosaic or mixed, and mosaic to mixed). The percentage of the ERU that remained in the same pattern class between historical and current periods was used to estimate a stability index. Conversely, a departure index for ERUs was calculated to quantify the magnitude of change between historical and current broad-scale physiognomic group patterns. The departure index was calculated by:

$$PD = 100 - \left[\frac{200 \Sigma_k \text{minimum} \left(h_k, c_k \right)}{\Sigma_k h_k + \Sigma_k c_k} \right]$$

where

PD = departure index,

k = number of classes,

h_k = the historical value for class k, and

c_k = the current value for class k.

ERU departure indices were classified on a relative scale as low, moderate, and high for values less than 33.3, 33.3 to 66.6, and exceeding 66.6, respectively.

Terrestrial community group patterns

Historical and current period patterns of broad-scale terrestrial community groups were assessed for the LCA, an area that extended slightly beyond the boundaries of the Basin (maps 3.1 and 3.2). The historical and current period vegetation maps were derived using different methods and resolutions (Menakis and others 1996). Consequently, comparisons of landscape patterns between historical and current periods were difficult. To ameliorate the problems associated with resolution, the 1-square-kilometer current and historical vegetation layers were resampled to 4-square-kilometer resolution, and the 24 terrestrial community types were further aggregated into 12 terrestrial community groups (table 3.9). We believe that using a coarser 4-square-kilometer resolution and a coarser classification of vegetation types improved the comparability of historical and current period vegetation patterns. As previously discussed, changes of riparian vegetation types between historical and current periods could not accurately be assessed. Consequently, pattern changes of any riparian community groups were not reported in this chapter.

FRAGSTATS (McGarigal and Marks 1994) was used to estimate class (that is, terrestrial community groups) and landscape metrics to assess pattern changes of the LCA as a whole, as well as pattern changes of each of the 12 community groups occurring within the LCA (table 3.10). Multiple metrics (that is, areal extent, largest patch index, patch number, and mean patch size) were evaluated to assess fragmentation. Indicators of an increase in fragmentation included decline in areal extent, a declining largest patch index, and a declining mean patch size, whereas the number of patches would generally be expected to increase. Conversely, indicators of a landscape becoming more homogeneous and contiguous included increasing areal extents, increasing largest patch index, increasing mean patch size, and declining numbers of patches. Because of the coarse resolution of this analysis and the different mapping methods involved, we assumed ecologically significant changes occurred when current period metrics deviated by 20 percent or more from historical metrics.

Forest and Rangeland Integrity

We conducted ancillary analyses to integrate the broad-scale data and develop an overall ecological integrity index of forest and rangeland ecosystems within the Basin. We could not measure ecological integrity directly. Consequently, relative integrity ratings were estimated from the departures

Table 3.9—Aggregation of 24 terrestrial community types into 12 terrestrial community groups for analysis of broad-scale changes in vegetation patterns.

Terrestrial Community Group	Terrestrial Community Type
Agriculture	Agricultural
Alpine	Alpine
Exotic Herbland	Exotic Herbland
Lower Montane Forest[1]	Early-seral Lower Montane[1] Forest
	Mid-seral Lower Montane[1] Forest
	Late-seral Lower Montane[1] Multi-layer Forest
	Late-seral Lower Montane[1] Single-layer Forest
Montane Forest	Early-seral Montane Forest
	Mid-seral Montane Forest
	Late-seral Montane Multi-layer Forest
	Late-seral Montane Single-layer Forest
Rock	Rock / Barren
Subalpine Forest	Early-seral Subalpine Forest
	Mid-seral Subalpine Forest
	Late-seral Subalpine Multi-layer Forest
	Late-seral Subalpine Single-layer Forest
Upland Herbland	Upland Herbland
Upland Shrubland	Upland Shrubland
Upland Woodland	Upland Woodland
Urban	Urban
Water	Water
NU[2]	Riparian Herbland
NU	Riparian Shrubland
NU	Riparian Woodland

[1]Originally referred to as Ponderosa pine Forest.

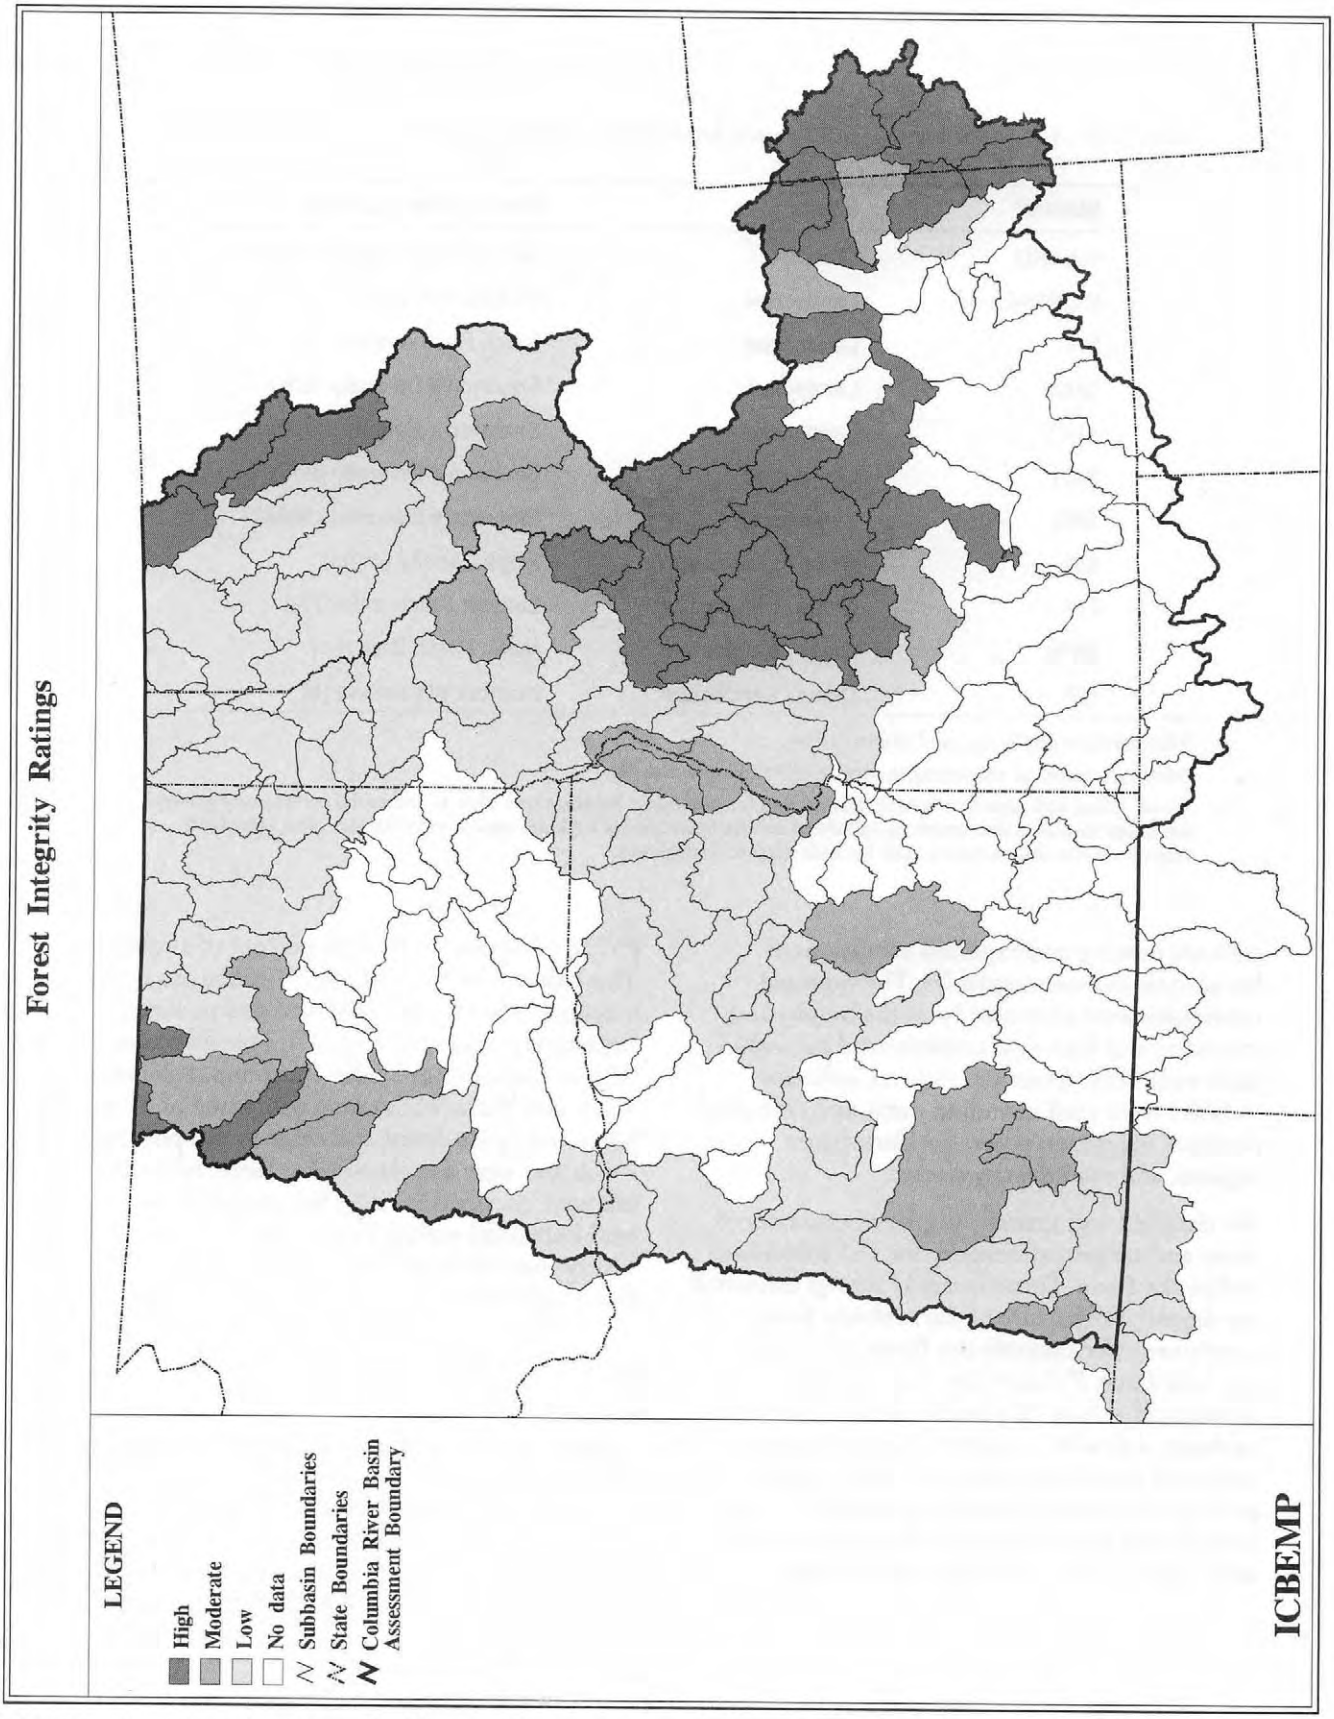
[2]NU = Not Used. Patterns were not assessed for the riparian terrestrial community types because these types generally occurred in scattered, relatively small- to medium-sized patches, and tended to be underestimated as mapping resolution increased. Consequently, because the historical vegetation layer was developed at a coarser resolution than the current period vegetation layer, it was likely that the two mapping efforts contained different biases. Therefore, changes of riparian vegetation types between historical and current periods could not accurately be assessed.

Table 3.10—Landscape metrics used to assess broad-scale vegetation patterns.

Metric[1]	Scale[2]	Description (units)
%LAND	Class	Percent of the landscape (%)
CONTAG	Landscape	Contagion Index
PR	Landscape	Patch Richness (#)
SHDI	Landscape	Shannon's Diversity Index
SHEI	Landscape	Shannon's Evenness Index
SIDI	Landscape	Simpson's Diversity Index
SIEI	Landscape	Simpson's Evenness Index
ED	Class / Landscape	Edge Density (m/ha)
LPI	Class / Landscape	Largest Patch Index (%)
MPS	Class / Landscape	Mean Patch Size (ha)
NP	Class / Landscape	Number of patches (#)

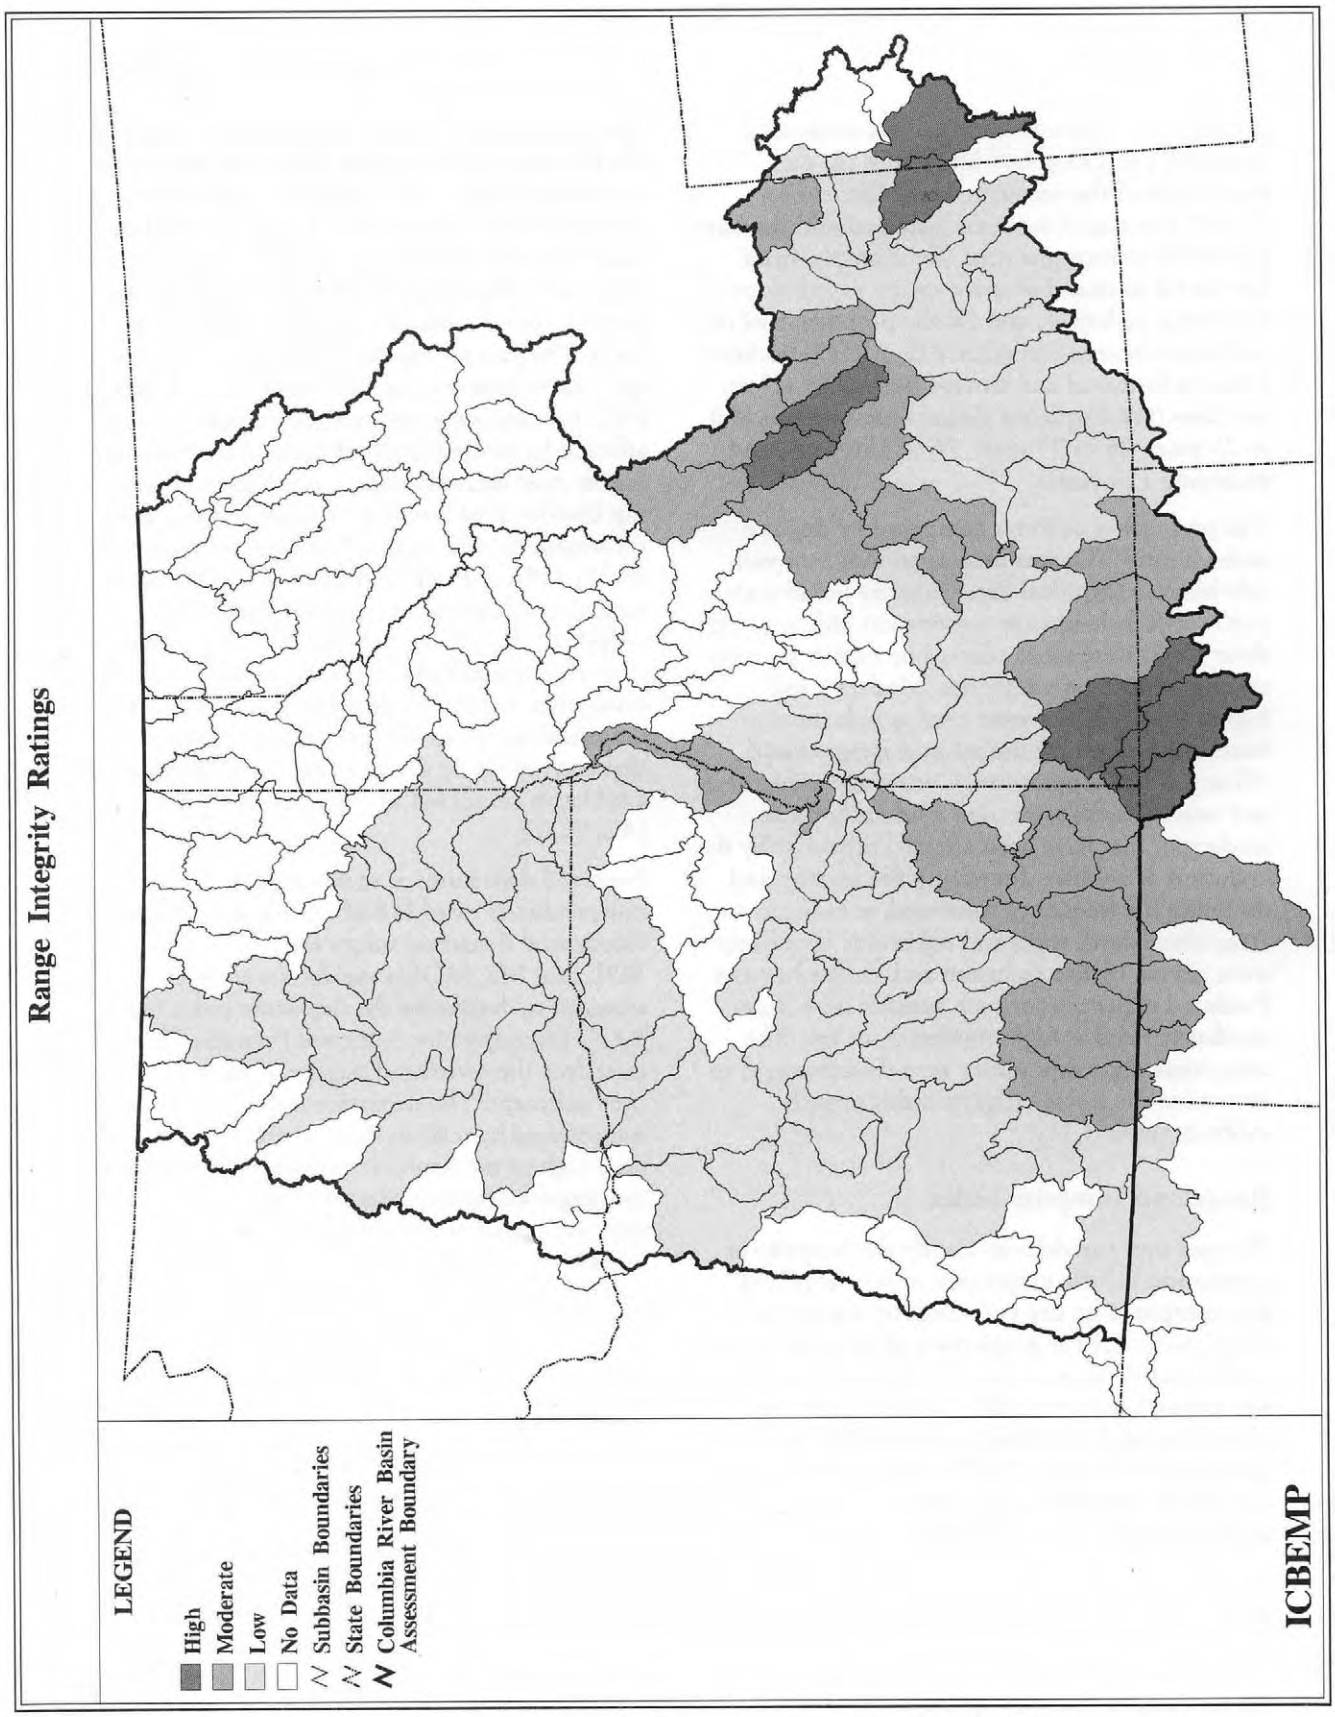
Adapted from McGarigal and Marks (1994).

[1]Metric: a means of measuring or specifying values of variability.



[2]Scale: Class indicates that metric is calculated for individual habitat types (that is, terrestrial community group); landscape indicates that metric is calculated for the landscape as a whole, regardless of habitat type; class/landscape indicates that metric is used for both class and landscape.

between existing and expected conditions of broad-scale indicator variables. The expected conditions were estimated from the biophysical templates and historical conditions of individual subbasins. Both direct and indirect indicator variables were used including forest and rangeland potential vegetation types, fire disturbance regimes, and road density classes.



We classified and spatially displayed estimates of forest and rangeland integrity for 163 subbasins within the Basin. Forest integrity ratings estimated the degree of departure of the subbasin forest component (for example dry forest, moist forest, and cold forest PVGs) when that component constituted at least 20 percent of the area of the subbasin. Likewise, rangeland integrity ratings estimated the relative integrity of the rangeland portion of subbasins when rangeland PVGs (for example dry grass, dry shrub, cool shrub, woodland, riparian shrub, and riparian woodland PVGs) composed at least 20 percent of a subbasin. This rule resulted in 112 and 91 subbasins with measurable forest and rangeland components, respectively (maps 3.8 and 3.9). Five subbasins (Upper Crab, Lower Snake-Tucannon, Palouse, Rock, and Walla Walla) were composed of 75 to 88 percent agricultural and other anthropogenic PVGs and were not classified as forest subbasins but were classified as range because of the rangeland imbedded within the agricultural lands. Thirty-nine subbasins were classified as both forest and rangeland.

Forest Integrity Index

Five indicator variables were used to classify the integrity of forests within subbasins: (1) the proportion of the forest area of subbasins composed by dry and moist forest PVGs (D+M/TOT); (2) the proportion of the subbasin that was estimated to have road densities of at least 0.43 kilometers per square kilometer (RD_MOD+); (3) the

Map 3.8—Forest integrity ratings of subbasins. These ratings were developed as relative indexes of ecological integrity.

Map 3.9—Rangeland integrity ratings of subbasins. These ratings were developed as relative indexes of ecological integrity.

proportion of the subbasin that was essentially unroaded (WILD ≤ 0.06 km/km^2); (4) the proportion of the subbasin where fire severity (F_SEV) increased between historical and current periods by at least one class (for example, from non-lethal to mixed severity, mixed to lethal, or non-lethal to lethal); and (5) the proportion of the subbasin where fire frequency (F_FREQ) declined between historical and current periods by at least one class (fire frequency classes were intervals of 0 to 25 years, 26 to 75 years, 76 to 150 years, and exceeding 150 years).

The proportion of forest composed by dry and moist forest PVGs was used as an indicator variable because empirical data from the broad-scale and mid-scale landscape assessments indicated that these PVGs were most affected by timber harvests and fire suppression activities. Moderate and higher road densities were used as indicators of established access for timber management and efficacy of fire suppression. Conversely, wilderness and roadless areas were used to identify those landscapes that have been affected primarily by the exclusion of wildfire. Increasing fire severity and declining fire frequency were used to indicate the areas where cover types and structures were likely most altered by fire exclusion and timber harvests. Predicted departures of each variable were independently rated as high, moderate, or low. The categorical departure values were then averaged to determine the forest integrity index of each subbasin (table 3.11).

Rangeland Integrity Index

We used four variables to classify the integrity of rangelands: (1) the proportion of the rangeland area composed by dry grass and dry shrub PVGs (Dry/TOT); (2) the proportion of the subbasin in which road densities were at least 0.43 kilometers per square kilometer (RD_MOD+); (3) the proportion of the subbasin composed by the agricultural PVG (AG/TOT); and (4) the proportion of the subbasin composed by the juniper-sagebrush cover type (Jun/TOT).

The proportion of rangeland PVGs composed by the dry grass and dry shrub PVGs was used as an indicator variable of rangeland integrity because empirical data from the broad-scale and mid-scale landscape assessments suggested that these PVGs were most affected by excessive livestock grazing pressure and the invasion of exotic grasses and forbs. The juniper-sagebrush (*Juniperus-Artemisia* spp.) cover type was used instead of the woodland PVG because the latter underestimated the area affected by juniper encroachment. Moderate and higher road densities were used to indicate increasing likelihood of invasion by some exotics, where incursions have been correlated with road densities (Baker 1986, Forcella and Harvey 1983). Lastly, agricultural conversion occurred primarily in rangeland ecosystems. We assumed that conversion of rangeland physiognomic types to agricultural types was the single greatest alteration of rangeland integrity. We estimated the extent of that conversion by determining the proportion of a subbasin composed by the agricultural PVG (AG/TOT).

Predicted departures of each variable were independently rated as high, moderate, or low. Categorical departure values for Dry/TOT, AG/TOT, and RD_MOD+ variables were then averaged to determine the departure index (table 3.12). The departure index was then modified to reflect the estimated degree of juniper encroachment. The departure index of a subbasin was reduced by 0.67 or 0.33 when juniper areas were high or moderate, respectively, to determine the rangeland integrity index. Juniper encroachment estimated as low did not alter the integrity index.

Table 3.11—Forest departure and integrity indices.

Departure Index[1]	Indicator Variables					Relative Integrity Index[7]
	D+M/TOT[2]	F_sev[3]	F_freq[4]	RD_ Mod+[5]	Wild[6]	
	Percent					
High (1)	>66	>66	>66	>66	<25	<1.8 (Low)
Moderate (2)	33 - 66	33 - 66	33 - 66	33 - 66	25 - 50	1.8 - 2.0 (Mod)
Low (3)	<33	<33	<33	<33	>50	>2.0 (High)

[1]Departure index = the departure of existing conditions from that expected from the biophysical templates and historical conditions.

[2]D+M/TOT = the proportion of the forest within the subbasin comprised of dry forest and moist forest PVGs.

[3]F_sev = the proportion of the subbasin in which fire severity increased by at least one class (that is, non-lethal to mixed, non-lethal to lethal, and mixed to lethal.

[4]F_freq = the proportion of the subbasin in which fire frequency decreased by at least one class. Fire frequency classes have intervals of: 0 to 25 years, 25 to 75 years, 75 to 150 years, and more than 150 years.

[5]RD_Mod+ = the proportion of the subbasin comprised of estimated road densities of at least 0.43 kilometer per square kilometer.

[6]Wild = the proportion of the subbasin comprised of roadless areas.

[7]Relative Integrity Index = average categorical departure values.

Table 3.12—Rangeland departure and integrity indices.

Departure Index[1]	Indicator Variables				Relative Integrity Index[6]
	Dry/TOT[2]	Ag/TOT[3]	RD_ Mod+[4]	Jun/TOT[5]	
	Percent				
High (1)	>66	>25	>66	>15	<1.68 (Low)
Moderate (2)	33 - 66	10 - 25	33 - 66	5 - 15	1.68 - 2.66 (Mod)
Low (3)	<33	<10	<33	<5	> 2.66 (High)

[1]Departure index was based on the comparison of existing conditions and that expected from the subbasin biophysical environment.

[2]Dry/TOT = the proportion of the rangelands within the subbasin comprised by dry shrub and dry grass PVGs.

[3]Ag/TOT = the proportion of the subbasin comprised by the agricultural PVG.

[4]RD_Mod+ = the proportion of the subbasin comprised by estimated road densities of at least 0.43 kilometer per square kilometer.

[5]Jun/TOT = the proportion of the subbasin comprised by the juniper-sagebrush cover type.

[6]Relative integrity index = average categorical departure values.

Regional and Landscape Similarities of Historical and Current Vegetation Conditions, and Succession/Disturbance Regimes

We assessed the degree of regional and landscape similarity between the historical and current conditions by using a similarity index computed by:

$$\text{Percent Similarity} = \left[\frac{200\Sigma_k \text{ minimum } (h_k, c_k)}{\Sigma_k h_k + \Sigma_k c_k} \right]$$

where

k = number of types,

h_k = the historical value for type k, and

c_k = the current value for type k.

The similarity assessment conducted at the regional level evaluated compositions of the broad-scale physiognomic types, succession/disturbance regimes, and fire regimes that existed during the current period with the compositions that were projected for the 400-year historical simulation. Regional similarities were evaluated for the Basin as a whole, as well as for BLM/FS lands within the Basin. Landscape similarities were conducted at the subbasin level and were stratified by landform, management class, and PVG. Vegetation conditions (such as, broad-scale physiognomic types, fine-scale data pertaining to tree and snag densities, canopy cover, fuel loading, and assumptions of mid-scale mosaic patterns) and succession/disturbance regimes similar to native, reserve, and traditional commodity management systems were assessed at the landscape level (figs. 3.11a, b, c; 3.12a, b, c; and 3.13a, b, c). We created a category for "Other" patterns of physiognomic types and succession/disturbance regimes because some areas had been converted to anthropogenic types (for example, agriculture, exotics, and urban), or physiognomic types that would not be expected to change between the historical and current periods. Very few areas having Other patterns occurred on BLM/FS lands. Landscape similarities were not determined for those areas within a subbasin that were classified as having Other patterns. Landscape similarities were determined for individual subbasins as a whole, as well as for the BLM/FS lands within each subbasin. Landscape similarities of BLM/FS lands were further stratified by the two EIS areas, three landscape mosaics, and six subbasin groups.

General Landscape Patterns

We developed a framework for the assessment and management of landscapes (that is, subbasins or smaller geographical areas) that linked disturbance regimes (including human uses) across multiple scales of time and space. We wanted to provide a classification system that would simplify the complexity of the spatial and temporal variation of biophysical conditions, vegetation composition and structure, and disturbance regimes (including human uses) across the wide variety of landscapes that occur within the Basin. Furthermore, we hypothesized that the classification scheme would be hierarchical, and that it could be mapped and interpreted consistently across any landscape scale (subbasins or smaller watershed delineation). To be useful, our classification system needed to be based upon relatively simple attributes that could be consistently identified throughout a wide variation in general landscape patterns. Although we recognized that the mechanistic processes regulating succession and disturbance regimes include biogeochemical processes and the mosaic patterns of the terrain, we used broad-scale correlates to explain the variability of landscape features that change in response to fluctuating processes across space and time.

We aggregated the nine subsection landforms developed by Nesser and Ford (1995) (map 3.10) into three broad-scale landforms (that is, mountains, foothills, and plains). Subbasins were classified by their composition of these broad-scale landforms. Classified subbasins were then categorized into three landscape mosaics based on their historical composition of forest and rangeland PVGs: forest, rangeland (or non-forest lands), and forest-rangeland landscape mosaics. These landscape mosaic classes served as correlates of coarse climatic conditions.

Map 3.10—Broadscale subsection landforms of the Basin. Landforms are based on the dominant subsection landform within subwatershed.

We developed generalized landforms based upon a modal watershed profile that accounted for most combinations of fine- and mid-scale landforms that occurred within the broad-scale landforms. Our classification of generalized landforms was based upon Holdorf and Donahue (1990), McNab and Avers (1994), Nesser and Ford (1995), Peterson (1981), and Rosgen (1994). We named the generalized landforms for ease of interpretation at the subbasin or finer scales. Iterative testing indicated that the generalized landforms provided a biophysical platform that was correlated with the patterns of succession and disturbance regimes, land use, and subsequent vegetation structures and composition (Hann and others 1997). The generalized landforms included:

- Ridge: areas that connect the tops of adjacent slopes, forming a divide between two watersheds. Ridges, for multi-scale purposes, can be narrow to broad, or steep to flat. Ridges typically have shallow or rocky soils and low soil moisture relative to the adjacent slopes. Ridges are always located adjacent to a slope. The slope break between the ridge and slope causes a reduction in upslope wind velocities.
- Slope: an inclined surface that generally has a vertical to horizontal ratio exceeding 10 percent. Slopes connect ridges to other landforms, usually a footslope. Slopes typically have soils that are deeper, less rocky, and more moist than ridges. Slopes typically have winds that are affected by broad-scale landforms. Generally, upslope winds occur during the afternoon and downslope winds occur at night. Slopes adjacent to wider valleys often are subject to thermal heating in the afternoon and thermal inversion during the night. Consequently, these slopes have a warmer environment, particularly in the summer, than would be expected. Steep slopes on river breaks are often influenced by upriver winds in the afternoon, and downriver winds at night.
- Footslope: the bottom end of a slope that is concave in shape. The footslope landform generally has deeper soils, and soils with higher moisture content than the adjacent slope, terrace, or plain. These landforms are commonly located in areas subject to alluvial and colluvial deposition. Footslope landforms often occur in areas where air inversions (that is, areas that retain cold air at night and in the early morning) are common. Winds are typically more erratic on footslope landforms, due to their concave profile, than on the adjacent slope, plain, or terrace landforms. Their concave shape may either impede the wind or promote wind gusts. Footslopes typically connect plain or terrace landforms to a slope, but can also connect a slope directly to a toeslope or channel zone/draw. Footslopes can also be found on gently rolling or inclined plains. Regardless of their position, the subsoil layer within footslopes causes the water table to be close to the surface.
- Terrace or plain: a flat or slightly inclined surface with generally less than a 10 percent slope. Typically these landforms have deeper soils containing fewer rocks than the ridge and slope landforms. Terraces are often affected by cold air inversion during the evening and early morning. Winds are typically controlled by the plain or valley broad-scale landforms. Terraces in valleys are generally subject to upriver winds in the afternoon and downriver winds at night. Plains adjacent to broad-scale mountain landforms are commonly influenced by relatively strong afternoon winds and windstorm events associated with the broad-scale plains and mountains landforms. A terrace will almost always connect a toeslope or channel zone/draw to a footslope or slope landform. A relatively narrow terrace is known as a bench. A plain, on the other hand, may or may not connect with a footslope or slope, but will generally connect with a toeslope or channel zone/draw. The terrace or bench is found within the subsection valley or basin landforms, in narrower valleys of mountains and foothills, and in valleys out in the plains. Terrace areas are commonly in the long-term floodplain. The plain is typically found in the broad-scale plains or basin landforms.

- Toeslope: this landform is a relatively steep incline that connects the slope, footslope, terrace, or plain to the stream channel. Soils are typically coarse. Toeslopes in narrow valleys or draws that connect terraces to channel zone/ draws may occur in the floodplain and can be inundated by floods or beaver ponds, whereas toeslopes in wider valleys may not be affected by flood waters.
- Channel zone/Draw: includes the area affected by the average annual wetted perimeter of intermittent or perennial streams. This is considered the active channel zone. The draw may be dry or have an intermittent stream channel, but usually has subsoil moisture and seeps or springs. Some dry draws may also be subject to alluvial or colluvial events.

The complexities of temporal landscape changes are related to the patterns of succession and disturbances. The succession/disturbance regimes (table 3.6) were correlated with general landforms, dominant PVGs, and land uses in order to identify repeatable relationships. The dynamic relationships among succession and disturbance regimes, landforms, and land uses were developed from various scales of paired oblique photographs from historical and more recent periods (Losensky 1995), field reconnaissance, aerial photos, and interpretations from plot data and photos (Hann and others 1997).

Of the variables tested, general landforms were the most strongly correlated (65%) with succession/ disturbance regimes. The predictability of succession/disturbance regimes was increased incrementally by adding the following variables to our hierarchical model:

1) potential for woody vegetation versus herbaceous vegetation;
2) potential life form (for example, a conifer tree, broadleaf tree, shrub, or herb);
3) management class (that is, the identified land ownership, type of management, and whether an area had been roaded or remained virtually unroaded) (see table 3.4);
4) physiognomic type or terrestrial community; and
5) potential vegetation group.

We did not observe strong correlations between fine-scale potential vegetation types and succession/disturbance regimes. This weak correlation was likely due to compensating environmental variables that can produce a similar environment for plants, but a very different environment for succession and disturbance. For example, a PVT with potential for Douglas-fir can occur on a south-facing bench or terrace with a frequent maintenance regime, as well as on a lower elevation north slope with an accelerated cycle regime. Another case would be a sagebrush PVT on a ridge landform with deep soils and a moderate cycle regime compared to a sagebrush PVT on a steep south-facing slope at higher elevation with a frequent maintenance regime.

We classified subbasins according to their dominant, coarse land-use patterns including traditional commodity or traditional reserve management strategies. These land-use strategies were compared to the native (or HRV) systems.

The native system was based on our understanding of the HRV, which in turn was developed from VDDT and CRBSUM simulations, mid-scale pattern analyses (Hessburg and others 1996a), historical oblique photos (Losensky 1995), the literature, and review of plot data (Hann and others 1997). Traditional commodity management was identified and described using information from modal areas dominated by traditional forestry or livestock management. Traditional reserve management was identified and described using information from modal areas dominated by wilderness and roadless area management objectives.

We described landscape patterns at the subbasin level which incorporated the dominating mosaic of PVGs (forest, rangeland, and forest-rangeland mosaics), general landforms, land-use patterns, vegetation structures, and succession/disturbance regimes.

Rangeland Ecology and Grazing Management

Factors Related to Rangeland Health and Broad-scale Vegetation Changes on Rangelands and Riparian Areas

Detailed reports were written by the project staff on specific topics in rangeland ecology and grazing management, primarily using source material from solicited external contract reports, solicited external peer reviews of selected external contract reports, published literature, and databases. Specific topics in rangeland ecology and grazing management were selected based on their relevance to: (1) rangeland health, which was identified within the "Purpose of and Need for Action" for the two EISs[1], and (2) potential broad-scale vegetation changes on rangelands and riparian areas emanating from landscape modeling and analyses. Specific topics included: woody species encroachment, particularly by western juniper; microbiotic crusts; livestock grazing in riparian areas; and exotic plant invasions (particularly by legally-declared "noxious" weeds). As reports were being written on these topics, three additional topics were selected that we deemed worthy of detailed reports: implications of livestock herbivory in the Basin, cheatgrass invasion, and indicators of susceptibility of rangeland health to management-induced disturbance stresses. These detailed reports were used as primary sources in the "Rangeland Ecology and Grazing Management" subsections of the "Results and Discussion" section of this chapter. Cheatgrass was addressed separately from the noxious weeds because cheatgrass, although an exotic plant, had not been legally declared a noxious weed in the Basin at the time this document was prepared. In addition, we determined that cheatgrass warranted more thorough discussion because of its great areal extent in the Basin and its pivotal role in disturbance regimes.

[1] Purpose of and Need for Action are sections within the Eastside and UCRB Draft Environmental Impact Statements, on file with: U.S. Department of Agriculture, Forest Service; U.S. Department of the Interior, Bureau of Land Management; Interior Columbia Basin Ecosystem Management Project, 112 E. Poplar, Walla Walla, WA 99362.

Solicited external contract reports and peer reviews are on file with the ICBEMP. External contract reports were subjected to external peer review if we believed the rangeland topic and content of the report were contentious, or the content was narrow in scope. Financial constraints did not permit external peer review of all external contract reports. External peer reviews were, in most instances, additional to peer reviews solicited by the author(s) of the contract reports. Our objectives in seeking external peer reviews were to obtain additional credible scientific documentation that the author(s) of contract reports might have overlooked, and to seek scientifically-substantiated viewpoints different from those presented. The author(s) was not disclosed to peer reviewers. Reports were not solicited for all topics; reports for cheatgrass invasion and indicators of susceptibility of rangeland health to management-induced disturbance stresses were primarily completed by the project staff.

The following lists solicited external contract reports and their solicited external peer reviews, by topic:

5) Exotic Plant Invasion

- Solicited Contract Report:

  Sheley, R.L., ed. 1994. The identification, distribution, impacts, biology and management of noxious rangeland weeds. 366 p.

We restricted our analysis of exotic plant invasions in the Basin to a set of 25 exotic plants (24 legally-declared noxious species and cheatgrass; see table 3.13), many of which were selected based on their inclusion in Sheley (1994). In addition, information was compiled on nine exotic plant species [one of which, squarrose knapweed (*Centaurea virgata*), was also included in the set of 25 species] that were selected based on their proposed status as new, or potentially new, exotic plant invaders of the Basin. Thus, information on exotic plant invasion was collected and analyzed for 33 species.

The basic components of our exotic plant invasion analysis included: (1) mapping of the areal extent of the 25 exotic plant species at the county level within the Basin; and (2) developing a Susceptibility to Invasion Index (for the 25 previously mentioned species) of the broad-scale cover types in the Basin. The Invaders database Release 6.2 (Karl 1995), published and unpublished literature, and personal observations by numerous exotic plant experts, were the primary sources used in this analysis.

The Invaders database is housed at the University of Montana and is maintained by Peter M. Rice,[2] a contractor of the ICBEMP. The Invaders database is a collection of distribution records of primarily exotic plant species that reside in Washington, Oregon, Idaho, Montana, and Wyoming. The Invaders database Release 6.2 contains 64,217 distribution records, of which 51,587 (80%) are for exotic plant species. Of these 51,587 records, 14,438 (28%) are for legally-declared noxious weeds. Of these 14,438 records, 7,445 (nearly 52%) pertain to the 24 noxious weed species included in table 3.13. The records were collected for the 199 counties, five-state area, of which only 97 counties lie totally or partially within the Basin. Thus, not all 7,445 records were collected within the Basin.

Distribution records were collected from an array of sources, including: five of the six largest regional herbaria (Oregon State University, Washington State University, University of Idaho, University of Montana, and Montana State University); State Department of Agriculture surveys, Animal and Plant Health Inspection Service (APHIS)/Cooperative Agricultural Pest Survey (CAPS) surveys; U.S. Forest Service Intermountain Region ECODATA and Pacific Northwest Region

Table 3.13—Exotic plant species found within the Basin that have a widespread county distribution or a somewhat restricted distribution [assessed in Karl and others (1995)]. With the exception of cheatgrass which has not been legally-declared noxious in the Basin, all species have been legally-declared noxious in at least one of these five states: Washington, Oregon, Idaho, Montana, and Wyoming.

Widespread[1]		Somewhat Restricted[2]	
Common Name	**Number of Counties[3]**	**Common Name**	**Number of Counties**
Bull thistle	71	Common crupina	6
Canada thistle	97	Dyers woad	33
Cheatgrass	97	Halogeton	11
Dalmatian toadflax	80	Mediterranean sage	16
Diffuse knapweed	84	Medusahead	37
Hoary cress (whitetop)	86	Orange hawkweed	23
Leafy spurge	72	Rush skeletonweed	48
Musk thistle	72	Squarrose knapweed	4
Oxeye daisy	48	Sulfur cinquefoil	35
Purple loosestrife	49[4]	Yellow hawkweed	18
Russian knapweed	83	Yellow starthistle	55
Scotch thistle	71[4]		
Spotted knapweed	92		
Yellow toadflax	69		

[1]At least one-third of the counties in Washington, Oregon, Idaho, and Montana have reported the presence of these exotic plant species.

[2]Exotic plant species reported in fewer than one-third of the counties, in at least one of the four above-mentioned states.

[3]There are a total of 97 counties represented within the five state (Washington, Oregon, Idaho, Montana, and Wyoming) portion of the Basin.

[4]Does not meet the criteria for "widespread" because the plant's reported distribution in Montana is in less than one-third of counties. However, its distribution is widespread in the other states.

Ecology Plots; and a survey of selected regional weed experts.[3] Additional distribution records were obtained from various publications, private collections, a partial data set from the Rocky Mountain Herbarium located at the University of Wyoming, and smaller regional herbaria.

County distribution maps for each of the 25 species in table 3.13 can be found in Karl and others (1995), and Rice and Rider (1995). County distributions were summarized in table 3.13. The county distribution maps were derived from 121 years (1875-1995) of records and included counties in which at least one distribution record for any of the 25 species showed a specific county where a species existed. Counties with distribution records were judged as having definitive presence of a species. Counties without distribution records, however, did not in our judgment provide proof of the absence of a species. The absence of distribution records for a species within a county did not equate to the absence of that species from the county.

[3] Unpublished data. Michael G. "Sherm" Karl. 1996. Rangeland Management Specialist-Ecologist, U.S. Department of Agriculture, Forest Service, Interior Columbia Basin Ecosystem Management Project, 112 E. Poplar, Walla Walla, WA 99362.

The Susceptibility to Invasion Index was compiled from the distribution records within the Invaders database, which were queried to determine the vegetation cover type associated with the distribution record. Several literature sources and the Fire Effects Information System database[4] were used to supplement the query of the Invaders database. The product of the query was a data matrix of 950 cells (38 cover types times 25 exotic plant species). Each cell contained a rating of susceptibility to invasion. The susceptibility ratings were determined at the cover type level because cover types represent vegetation that presently exists on the land surface. Cover types are a result of natural and anthropogenic disturbances. As such, cover type susceptibilities are useful to land managers and others who are interested in detecting infestations of these exotic plant species. The ratings and their definitions are:

- H = High susceptibility to invasion: Exotic plant species invade the cover type successfully and become dominant or codominant even in the absence of intense or frequent disturbance. These exotic plant species are categorized as "invaders" (Bazzaz 1986) to the cover type.
- M = Moderate susceptibility to invasion: Exotic plant species invade the cover type successfully because a high-intensity disturbance or frequency of disturbance alters the soil surface or vegetation cover. These exotic plant species are categorized as "colonizers" (Bazzaz 1986) to the cover type.
- L = Low susceptibility to invasion: Exotic plant species typically do not establish successfully because the cover type does not provide suitable habitat.
- U = Unknown susceptibility to invasion: Several factors could have led to this rating. Distribution data for the species might have been insufficient to permit a susceptibility rating, or ecological requirements of the species might not be available. The cover types associated with the distribution records might be poorly defined, or the cover type might be a minor areal component of the Basin so that the probability of obtaining records within it is exceedingly low.

Susceptibility ratings were proposed for each cell in the matrix if any information judged to be pertinent to the cover type was available. We propose that this resulted in a rather liberal portrayal of susceptibility to invasion, especially where information on susceptible habitats from source material was reported in a coarse context (for example, shrub-grassland or arid rangeland). Judgments were made as to what cover types should be included when coarse habitats were referred to as susceptible.

The Susceptibility to Invasion Index was linked with precipitation data to produce maps of the susceptibility of the Basin to invasion by five exotic plant species including cheatgrass, diffuse knapweed, leafy spurge, spotted knapweed, and yellow starthistle. The cover type theme (ICBEMP GIS CRBSUM Current Vegetation Cover Types Theme[5]) was linked to the "high," "moderate," "low," and "unknown" ratings of the Susceptibility to Invasion Index. These cover type/susceptibility couplets were then overlaid with precipitation zones derived from PRISM precipitation data (ICBEMP GIS Climate-PRISM Precipitation Data Theme[6]) to produce the maps. Precipitation ranges used for these species were 150 to 560 millimeters for cheatgrass, 150 to 890 millimeters for diffuse knapweed, 300 to 760 millimeters for spotted knapweed, and 300 to 635 millimeters for yellow starthistle. Information on precipitation

range for leafy spurge was not available, so only the Susceptibility to Invasion Index was used to produce its map. The "none" category in the maps included cover types with an unknown susceptibility rating; portions of cover types that lie outside the precipitation range of the species; and the barren, water, and urban cover types, which were cover types not included in the analysis. The maps do not spatially delineate the individual cover types in each susceptibility category. However, in the "Exotic Plants-Noxious Weeds" subsection of the "Results and Discussion" section of this chapter, we provide interpretation of the cover type extents in the high susceptibility category for these five species on an ERU scale.

Susceptibility of rangeland health to management-induced disturbance stresses

The National Research Council (NRC), in its text on rangeland health (National Research Council, 1994), defines rangeland health as "the degree to which the integrity of the soil and the ecological processes of rangeland ecosystems are sustained." We compiled information from several sources, primarily Leonard and Karl (1995c, 1995d), Pellant (1996), and U.S. Department of Agriculture (1993),[7] to propose indicators of susceptibility of rangeland health to management-induced disturbance stresses (for example, excessive livestock grazing pressure). We focused on soil properties and climate indicators that could be evaluated from existing coarse-grained data. Soil property indicators included (1) erodibility by water, (2) erodibility by wind, (3) salinity, (4) sodicity, and (5) shrink-swell potential (SSP). Climate indicators included the greater-than-30-centimeters annual precipitation zone, the 25-to-30-centimeters precipitation zone, and the less-than-25-centimeters precipitation zone. These indicators suggest varying levels of inherent "natural" stress in the biophysical system. An increase in the inherent natural stress of the biophysical system is proposed here as conferring a greater level of susceptibility of rangeland health to management-induced disturbance stresses.

Soil property indicators—

1) Erodibility by water: Susceptibility of rangeland health to management-induced disturbance stresses is somewhat dependent on the inherent erodibility of the soil. The soil erodibility factor (K factor) is a measure of the susceptibility of a soil to particle detachment and transport by rainfall. It is a quantitative value that is experimentally determined. A K factor exceeding 0.37 has been used by the Natural Resources Conservation Service (NRCS) as a limiting factor or erosion hazard (USDA 1983). We categorized all soils with a K factor of 0.37 or greater as indicative of a moderate level of inherent natural stress and a moderate susceptibility of rangeland health to management-induced disturbance stresses.

2) Erodibility by wind: A wind erodibility group (WEG) is a collection of soils that have similar properties affecting their resistance to wind. Of the nine WEGs recognized in the STATSGO database (USDA 1993), soils in wind erodibility Groups 1, 2, and 3 are relatively more susceptible to erosion by wind than soils in the remaining groups. We categorized soils in these WEGs as indicative of a moderate level of inherent natural stress and a moderate susceptibility of rangeland health to management-induced disturbance stresses.

3 and 4) Salinity and sodicity: Salinity and sodicity affect plant growth. Both can exacerbate the deleterious effects of soil surface disturbances on plant re-establishment. Salinity is the concentration of all salts more soluble than gypsum, whereas sodicity relates specifically to exchangeable sodium. High concentrations of salts can interfere with the absorption of water by plants and with the exchange capacity of nutrient ions, thereby resulting in nutritional deficiencies. Activities that disturb the soil surface and result in reduced infiltration and greater evaporation rates can lead to greater surface concentrations of salts. The

[7] Also, unpublished data. 1995. Kelly Redmond, Climatologist, Western Regional Climate Center, Atmospheric Sciences Center, Desert Research Institute, PO Box 60220, Sage Building, 5625 Fox Avenue, Reno, NV 89506.

greater surface concentrations of salts exacerbate the negative effects of salts on plant establishment and growth.

The sodium adsorption ratio (SAR) is the standard measure of sodicity. The SAR is the proportion of sodium relative to other cations, and is calculated as:

$$SAR = Na^{+} / \left[\frac{\sqrt{Ca^{2+} Mg^{2+}}}{2} \right]$$

with the cation concentrations presented as milliequivalents per liter (meq/l). Sodic, or alkaline soils, are characterized by a SAR of 13 or greater. The dispersal effect on soil particles attributable to the sodium in sodic soils results in a breakdown of soil structure. Sodic soils, when dry, form large crusty clods that inhibit seedling emergence. When wet, sodic soils have low infiltration and percolation rates. The physical crusting when dry, and the low infiltration rates when wet, hinder plant establishment on these soils. We categorized soils with a SAR of 5 to 12 and/or salinity of 8 to 16 mmhos/cm as indicative of a moderate level of inherent natural stress and a moderate susceptibility of rangeland health to management-induced disturbance stresses. We categorized soils with a SAR exceeding 12 and/or salinity exceeding 16 mmhos/cm as indicative of a high level of inherent natural stress and a high susceptibility of rangeland health to management-induced disturbance stresses. These categorizations are consistent with other interpretations of the limitations of these soil properties to plant growth and establishment of seedings.

5) Shrink-swell potential (SSP): Shrink-swell potential is the susceptibility of soil to volume change attributable to a loss or gain in moisture content. The SSP is related to the type and amount of clay. The SSP is expressed as the change (in percent) in linear extensibility (LE), or as the change (in decimal fraction) of the coefficient of linear extensibility (COLE), from a moist to a dry state. The COLE is calculated as:

COLE = (length of moist sample/length of dry sample) - 1.

Shrinkage of soils characterized by a high SSP (represented by a LE of 6 to 9, or a COLE of 0.06 to 0.09), and soils characterized by a very high SSP (represented by a LE exceeding 9 or a COLE exceeding 0.09), can damage plant roots and limit establishment of many perennial plants. Soils with high or very high SSP are particularly susceptible to invasion by exotic annual plants that have fibrous root systems (for example medusahead) and persist for only one year in place. We categorized soils with a high SSP as indicative of a moderate level of inherent natural stress and a moderate susceptibility of rangeland health to management-induced disturbance stresses. We categorized soils with a very high SSP as indicative of a high level of inherent natural stress and a high susceptibility of rangeland health to management-induced disturbance stresses.

The five soil property indicators were spatially portrayed in the Basin using soil map units derived from the state soil geographic database (STATSGO; USDA 1993). A soil map unit is a delineation on a map of an area dominated by one or more major kinds of soil, or miscellaneous areas (for example, a rock outcrop, or riverwash) that have essentially no soil and support little to no vegetation, or both. Soil map units are named by the taxonomic classification (typically, the soil series) of the dominant soil or miscellaneous area. Map units are individual; each has properties and characteristics that permit it to stand alone. Map units are described in soil surveys published by the NRCS. Soil surveys were not available for the entire Basin, therefore continuous coverage soil-survey level information was not available for the Basin.

Broad-scale assessment of the five soil property indicators that we judged to be indicative of susceptibility of rangeland health to management-induced disturbance stresses was obtained from a more generalized continuous coverage of soils from the STATSGO database. Map units in the STATSGO database typically cover a large area (hundreds to thousands of hectares). They are generally associations of several soil series and are derived from map units described in available soil

surveys from the NRCS, supplemented with schematic data from other sources. STATSGO soils information is general and useful in broad-scale land-use planning and broad-scale identification of areas that are suitable or unsuitable for a variety of uses.

We restricted our spatial portrayal of the soil property indicators to STATSGO soil map units that had at least 75 percent of the soils characterized by one or more of the five soil property indicators. Thus, some soil map units that had less than 75 percent of the soils characterized by a particular soil property indicator were not included. This represents a rather conservative estimate and portrayal of the spatial extent of soils characterized by these soil property indicators. However, we judged this to be suitable to focus attention on the most concentrated, regional areas of susceptibility of rangeland health to management-induced disturbance stresses in the Basin, as indicated by these soil property indicators. Various combinations of soil property indicators were able to be spatially portrayed because soil map units typically had at least 75 percent of the soils characterized by more than one of the five soil property indicators. The 13 soil property indicator(s) that were spatially portrayed are:

1. Erodibility by water.
2. Erodibility by water, and salinity of 8 to 16 mmhos/cm.
3. Erodibility by water, and salinity of 8 to 16 mmhos/cm, and erodibility by wind.
4. Erodibility by water, and high shrink-swell potential, and erodibility by wind.
5. Erodibility by wind.
6. Erodibility by wind, and erodibility by water.
7. Salinity of 8 to 16 mmhos/cm.
8. Salinity of 8 to 16 mmhos/cm, and erodibility by wind.
9. Salinity of 8 to 16 mmhos/cm, and high shrink-swell potential.
10. Salinity of 8 to 16 mmhos/cm, and sodicity (SAR of 5-12).
11. Salinity of 8 to 16 mmhos/cm, and sodicity (SAR of 5-12), and high shrink-swell potential, and erodibility by wind.
12. High shrink-swell potential.
13. High shrink-swell potential, and erodibility by wind.

STATSGO soil map units contained information about the 13 individual or sets of soil property indicator(s). Thus, 13 soil maps indicating various types of stress were portrayed. For clarification, soil map units portrayed for Number 5 (erodibility by wind) were not the same soil map units that were portrayed for any of the other numbered combinations that included erodibility by wind (for example, Numbers 3, 4, 6, 8, 11, and 13). Soil map units portrayed for Number 5 had a 75 percent or greater areal extent of soils characterized by wind erodibility, but none of the remaining four soil property indicators were present in the soils over 75 percent or greater of their extent. For combinations of indicators, for example for Number 11, a soil map unit had to have at least 75 percent of its soil extent characterized by all four of the soil property indicators.

Spatial extents of soils with these soil property indicators were reported and interpreted on an ERU basis, using percent coverage of the ERU. Spatial portrayal of the soil property indicator combinations required special interpretation: we could not assume that the entire extent of soils characterized by an individual soil property indicator also were characterized by other soil property indicators. We judged it safe to assume however, that because we restricted the inclusion of soil map units for analysis to those that had at least 75 percent of the soils characterized by soil property indicators, substantial overlap of soil property indicators could be located within the soil map unit.

Climate indicators—

Climatic factors indicative of rangeland health susceptibility to management-induced disturbance stresses included aridity, frequency of drought, and frequency of favorable periods of precipitation for perennial plant emergence and establishment. These climate factors, supplemented with successional recovery concepts in arid and semi-arid zones, were interpreted and molded into climate indicators, which are zones of annual precipitation greater than 30 centimeters, 25 to 30 centimeters, and less than 25 centimeters. We categorized the greater than 30 centimeters zone as indicative of a moderate to low level of inherent natural stress and a moderate to low susceptibility of rangeland health to management-induced disturbance stresses. In this category, the continuum of susceptibility from moderate to low is a reflection of greater amounts of precipitation received. We categorized the 25-to-30-centimeters zone as indicative of a moderate level of inherent natural stress and a moderate susceptibility of rangeland health to management-induced disturbance stresses, and the less-than-25-centimeters zone as indicative of a high level of inherent natural stress and a high susceptibility of rangeland health to management-induced disturbance stresses.

Frequency of drought and frequency of favorable periods of precipitation for perennial plant emergence and establishment were reported for each of 22 climate divisions existing within the Washington, Oregon, Idaho, Montana, and Wyoming portions of the Basin. Data on precipitation for the 100-year (1895-1994) period for these climate divisions were obtained from the Western Regional Climate Center[8]. Precipitation data were supplied by climate division, month, and year. Monthly precipitation data represented the total amount of precipitation for the 6-month period commencing with the primary month indicated; for example, a value of 26 inches (66 cm) for January 1894 meant that 26 inches (66 cm) of precipitation were received during the 6-month period of January through June 1894. The second 6-month precipitation period extended from February through July, the third from March through August, and so on. Median precipitation levels were calculated for each of these 12, 6-month precipitation periods over a 100-year timeframe. We used the greatest 6-month period of median precipitation for each climate division as the basis for calculating frequency of drought and frequency of favorable precipitation periods for perennial plant emergence and establishment. Drought years were those in which less than 75 percent of the median precipitation was received (for the wettest 6-month period). Favorable precipitation periods for perennial plant emergence and establishment were those in which at least 110 percent of the median precipitation was received (for the wettest 6-month period) for two or more years in succession.

Spatial portrayal of individual or various combinations of soil property indicators was intersected with the climate indicators as follows:

1) Soil map units, or portions of soil map units, lying within the less-than-25-centimeters precipitation zone were categorized as indicative of a high level of inherent natural stress and a high susceptibility of rangeland health to management-induced disturbance stresses. In many instances this raised the susceptibility rating from moderate to high, particularly where a soil property indicator (indicative of a moderate susceptibility of rangeland health to management-induced disturbance stresses) was present within the less-than-25-centimeters zone. Thus, in these instances, the climate indicator overrode the soil property indicator in the determination of the susceptibility rating;

2) Soil map units, or portions of soil map units, lying within the 25-to-30-centimeters precipitation zone were categorized as indicative of a moderate level of inherent natural stress and a moderate susceptibility of rangeland health to management-induced disturbance stresses; and

[8] Unpublished data. 1995. Kelly Redmond, Climatologist, Western Regional Climate Center, Atmospheric Sciences Center, Desert Research Institute, PO Box 60220, Sage Building, 5625 Fox Avenue, Reno, NV 89506.

(3 Soil map units, or portions of soil map units, lying within the greater-than-30-centimeters precipitation zone were categorized as indicative of a moderate-low level of inherent natural stress and a moderate-low susceptibility of rangeland health to management-induced disturbance stresses. As mentioned previously, susceptibility of these lands could shift from moderate to low as precipitation increased. However, the presence of soil property indicators on these lands, particularly in combination on the same land, tends to increase the level of inherent natural stress and shift the susceptibility in the opposite direction, from low to moderate.

Modeling Dynamics of the HRV and Management Prescriptions

The CRBSUM landscape model was used to simulate spatial and temporal dynamics of vegetation, associated disturbances, and related resource and habitat effects. CRBSUM used a multiple pathway approach to model succession and disturbance dynamics where succession classes were linked along succession and disturbance pathways. A succession class was described by a cover type and a structural stage.

Disturbance usually caused a change in succession class, altering the pathway that succession follows in the absence of disturbance. Disturbances were modeled stochastically in CRBSUM using probabilities that were stratified both spatially and temporally, given a certain scenario and management class (table 3.4). A scenario defined the limits of a broad-scale, general, land-management strategy. The "historical (native or HRV) scenario" depicted successional and disturbance processes prior to the extensive influence of Euro-American settlement. The "passive scenario" reflected minimal commodity production, where lands were predominantly used for recreation, education, and research. In the "consumptive demand scenario," the goal was to maximize commodity production through grazing, timber harvest, and other management practices. The "active management scenario" focused on the maintenance and restoration of native ecosystem functions and processes based on the landscape ecology model of contextual opportunity and risk for proper functioning landscape systems (PFS).

Management classes represented a relatively homogeneous, coarse, management area that reflected similar sets of disturbance activities (table 3.4). Management classes were stratified by "wilderness-like"[9] lands and "non-wilderness" lands. The historical (native or HRV) scenario had only one management class, wilderness-like lands, since disturbance probabilities did not vary geographically due to various management strategies.

Scenarios were designed by adjusting disturbance probabilities by PVT, succession class, and management class to reflect a long-term land-management policy. Within a scenario, each disturbance probability was conditional on the management class. PVT and succession class may have also affected the disturbance probability where, for instance, structural stages in moist, productive PVTs with high timber volume, would more likely be harvested given a certain scenario. Each scenario and management class combination had a unique set of probabilities that determined a succession and disturbance regime for a particular PVT.

Initial successional pathway development and fine tuning of disturbance probabilities used a PC-based succession model, the Vegetation Dynamics Development Tool or VDDT model (Beukema and Kurz 1995). The VDDT used the same algorithms as the CRBSUM and allowed the user to evaluate one PVT at a time. Through a series of workshops that assembled a wide range of forest and rangeland ecologists and resource specialists, over 80 succession models were developed that predicted the succession dynamics of the vegetation within the Basin (Hann and others 1997, Keane and others 1996b, Long and others 1996). The workshop participants defined broad-scale groupings of forest and rangeland potential

[9] In this case the term "wilderness-like lands" is synonymous with "wilderness lands," and "non-roaded areas," and natural process or natural/human process management classes.

vegetation types and assigned successional and disturbance pathways and associated disturbance probabilities. Succession and scenario files developed in the VDDT model were imported into a database and then into the CRBSUM.

Individual probability sets were analyzed and refined using a series of database queries and reference tables, which served to aggregate individual disturbances into disturbance groups. Disturbance groups (table 3.14) represented aggregations of approximately 200 possible disturbances in the CRBSUM. They were useful indicators of a probability set's emphasis on natural and human-caused disturbances and portrayed differences between probability sets. Disturbance group probabilities originated from the probabilities of individual disturbances for every PVT, cover type, and structural stage in a scenario. These probabilities were summed for each unique PVT, cover type, and structural stage combination for each disturbance group. The probabilities of disturbance groups were then averaged across groups of PVGs, and physiognomic types and groups of physiognomic types (aggregations of structural stages and cover types). Summaries of probabilities associated with groups of disturbances were calculated for each scenario.

CRBSUM simulations were also used to evaluate succession and disturbance regimes for each scenario across three generalized subbasin groups within the Basin: the Cascade Mountains, the Rocky Mountains, and the Intermountain region (see table 3.1). Area of disturbance, averaged by decade for a 100-year CRBSUM run for each of the disturbance groups, was summarized across these land areas to characterize disturbance regimes associated with each scenario. The historical scenario data were from a 400-year CRBSUM simulation, with average disturbance hectares calculated using output from years 50, 100, 200, 300, and 400. Distribution of vegetation types representing the average of year 50 and year 100, resulting from long-term management under each scenario, was used to characterize successional regimes. Historical scenario data for average vegetation distribution were from the 400-year CRBSUM simulation and results were calculated using years 50, 100, 200, 300, and 400.

The primary objective of the CRBSUM simulations was to contrast trends in landscape changes as a consequence of alternative land management strategies within the entire Basin. The scenarios were designed so that the CRBSUM simulation would span a range of acceptable management strategies within the Basin, and bounded the extremes of environmental effects for any subsequent management alternative designed for the EISs. A management alternative was a viable, broad-scale, land-use scheme tailored specifically for each management class. All of the initial probability sets developed under the scenarios for each PVT were evaluated through an iterative process of summarizing output from VDDT and CRBSUM simulations. This process resulted in the construction of 18 different "management prescriptions" for each PVT. The prescriptions were designed to cover a continuum of simulation conditions and were arrayed to portray differences in management emphases (table 3.15). The emphases were categorized into "conserve," "restore," "produce" classes or combinations of these classes (table 3.16). In general, conserve was a strategy that would have either minimal active management in areas like reserves, or low levels of active management to maintain or restore ecological conditions. Restore was a strategy involving active ecological restoration and maintenance, producing commodity and resource values where applicable. Produce was a strategy for active commodity production with little emphasis on ecological values. In general, the prescriptions were based on various mixtures of management strategies that emphasized either natural-disturbance processes that maintained native composition and structure, or human-disturbance processes that maintained or departed from native composition and structure.

Table 3.14—Disturbance groups and associated disturbance categories used for analyzing disturbance trends.

Disturbance Groups	Disturbance Categories
Commercial Timber Harvest	Even-age cut[1] with no site preparation
	Even-age cut with site preparation
	Even-age cut with reserve trees
	Shelterwood cut
	Shelterwood cut with reserve trees
	Overstory removal
	Group selection cut
	Individual selection cut
	Partial cut
	Commercial thinning
Exotics	Exotic annual grass
	Exotic forb
Non-impactive Grazing	Successional maintenance, big game grazing
	Successional acceleration, big game grazing
	Successional maintenance, livestock grazing
	Successional acceleration, livestock grazing
Pre-commercial Thinning	Pre-commercial thinning from below (younger, smaller trees)
	Pre-commercial thinning from above (older, larger trees)
Prescribed Fire	Prescribed lethal fire
	Prescribed mixed-severity fire
	Prescribed maintenance (underburn) fire
	Prescribed non-lethal fire
Seeding / Control of Exotics	Herbicide application and seeding
	Vegetation manipulation and seeding
Successional Change Grazing	Successional change, big game grazing
	Successional change, livestock grazing
Wildfire	Wild stand-replacing fire
	Wild mixed-severity fire
	Wild underburn
	Non-lethal wildfire

[1]Examples of even-age cuts are clearcut, seedtree cut, or combinations of cuts that mimic low-frquency, high-intensity fire events.

Table 3.15—Management prescription sets (Rx) for Historic Range of Variability (HRV) and scenario modeling.

Rx	Description
HI	Prescription set to model 100-year and 400-year simulations of HRV.
Ecological Restoration Prescriptions	
A1	Prescription set with moderate levels of ecological restoration. Generally designed for areas that have moderate to high departure from HRV, in roadless or conservation areas.
A2	Prescription set with moderate levels of ecological restoration. Generally designed for areas that have moderate departure from HRV, in areas with road access.
A3	Prescription set with moderate levels of ecological restoration. Generally designed for areas that have high departure from HRV, in areas with road access.
N1	Prescription set with low levels of ecological restoration. Generally designed for maintenance of areas that have low departure from HRV.
N4	Prescription set with low levels of ecological restoration typically for use in visually sensitive areas or where the objective has mixed traditional and ecological restoration objectives. Generally designed for areas that have low departure from HRV.
Traditional Reserve Management Prescriptions (wilderness and semi-primitive roadless areas)	
C1	Prescription set for traditional wilderness, park, and semi-primitive area management with minimal ecological mitigation.
N6	Prescription set for traditional wilderness and semi-primitive area management with minimal ecological mitigation.
P1	Prescription set for traditional reserve management with low probability of successful wildfire suppression.
Traditional Commodity Management Prescriptions	
C2	Prescription set for traditional commodity and resource value production at high levels with some ecological mitigation.
C3	Prescription set for traditional commodity and resource value production at high levels with no ecological mitigation.
N3	Prescription set for traditional commodity and resource value production at moderate levels and some ecological mitigation with higher livestock grazing than N8, and low probability of successful wildfire suppression.
N5	Prescription set for moderate level traditional commodity and resource value production with low emphasis on exotic weed control on rangeland.
N8	Prescription set for traditional commodity and resource value production at moderate levels and some ecological mitigation.
P3	Prescription set for traditional commodity and resource value production at very high levels with no ecological mitigation.
Traditional Management in Visually or Environmentally Sensitive Areas Prescriptions	
N2	Prescription set for moderate level traditional commodity and resource value production in visually sensitive areas with somewhat higher livestock grazing than N7 and minimal ecological mitigation.
N7	Prescription set for moderate level traditional commodity and resource value production in visually sensitive areas with minimal ecological mitigation.
P2	Prescription set for minimal levels of management in visually sensitive areas with no ecological mitigation and low probability of successful wildfire suppression.

Table 3.16—Management prescriptions (Rx) sorted by conservation, restoration, and production emphasis.

Rx Emphasis	Rx Ability to Achieve Emphasis	Management of Forest Non-Wilderness/ Roaded	Management of Range Non-Wilderness/ Roaded	Wilderness/ Non-Roaded Management
		Prescription		
Conserve	High	N1	N1	N1
	Moderate	N4	N4, C1	N6[1]
	Low	P1	P1	C1, P1
Conserve - Produce	High	N2, N7	N4	C1
	Moderate	N4 > N5[2]	N1	N1
	Low	P2[1]		N6
Produce	High	P3 > C3 > C2	C3	C1
	Moderate	N8, N3	N2, N3	N6
	Low	N7 > N5 > N4		
Restore	High	A2	A2	A1
	Moderate	A1	A3	N1
	Low	N4	N1	
Restore - Conserve	High	A1	A2	A1
	Moderate	N1	N1	N1
	Low	N4	N4	
Restore - Produce	High	A3	A3	A1
	Moderate	A2	A2	
	Low	N2 > N4 > N5	N1	N1

Proper Functioning Landscape Systems

Proper functioning landscapes include those landscapes whose processes are in dynamic equilibrium (including the production of human values), such that the rates and routes of key processes are resilient and respond predictably to disturbances.

We simulated historical conditions to approximate the native disturbance regimes and vegetation conditions (that is, HRV) at the subbasin scale. Future projections of landscape conditions included the short-term (1st decade) and the long-term (50 to 100 year period). We projected effects assuming a traditional independent limits model for the consumptive demand and passive scenarios, and an ecological model for the active ecological management scenario. We assessed outcomes of selected variables that integrated key ecological systems across the landscape template (background information in appendix 3-M).

The assessment of PFS requires the integration of the key variables responsible for landscape responses to disturbances, and planned (for example, silvicultural treatments) as well as stochastic (for example, drought) events.

To facilitate understanding of the complex, hierarchical, ecological and landscape relationships, no more than six strata should be used to compare

landscapes or management options. If more strata are required to assess conditions then one or more of the first six strata can be subdivided. Stratification should be based on the "driving"[10] variables within the assessment area. PFS provides a process for qualitative as well as quantitative landscape assessment. A qualitative "mockup" may be useful to develop a plan to assess PFS in a quantitative manner.

To assess PFS we emphasized landscape spatial and temporal patterns in relation to integrated succession and disturbance regimes, because of their analytical power for multiple scale assessment. We used a process of assessing landscape pattern responses by assessing succession/disturbance regimes within and between biophysical environments (PVGs). Traditional landscape analysis methods reduce variation in landscape patterns and processes by stratifying environments based on potential vegetation and landform. However, to assess proper functioning landscapes we needed a classification system that addressed the complexity of human, hydrologic, carbon-nutrient, food-web, and evolutionary interactions, yet did not overwhelm us with excessive stratifications. The combination of biophysical environment classifications and types of disturbance-specific regimes produced excessive stratifications. In addition, the wide variety of biophysical environments and associated landscape interactions often compensated to produce the same landscape pattern. The classification of landscape succession/disturbance regimes provided an analytical platform that simplified complex ecological interactions.

Transition to PFS and associated conditions of dynamic equilibrium were based on understanding the interactions of ecological elements, functions, and processes within the constraints of the landscape template. Through modeling outcomes for many different combinations of conditions and management strategies we concluded (as hypothesized in the introduction of this chapter) that there are two basic management models: the traditional independent limits management model (referred to as the traditional model) and the ecological landscape contextual and risk managment model (referred to as the ecological model). The traditional management model includes both management for commodities and management for reserves. Although these two types of traditional management on the surface would appear to have very different outcomes, both result in trend toward disequilibrium. This is because these types of management identify specific elements for commodity production or reserve protection and invest human energy to achieve the objective without considering the interrelationships with the other ecological elements, functions, and processes, or the constraints of the landscape in time and space.

We assessed the effects of management scenarios on PFS only for BLM- and FS-administered lands. For the evaluation of properly functioning systems, we used 20 variables that were integrated or direct measures of the key ecological systems and the landscape template. The first three variables suggest a trend toward proper functioning landscape patterns for range, forest, or forest-range types of landscapes. This pattern classification provides an integration of land use (indicator for the human system), type of biophysical environment and upland-to-channel landform relationships (indicator for hydrologic and land systems), and vegetation structures and succession/disturbance regime (indicators for carbon-nutrient and coarse-filter food-web/evolutionary systems).

The landscape pattern variables indicate the equilibrium relationships of the landscape template, since it is important that the succession/disturbance regimes and vegetation structures be in the right place in the landscape (for instance, the multi-layer old forest conditions belong on the moist footslopes where there is a maintenance succession/disturbance regime, not on the dry slope where there is a cycling regime). For wildlands, the PFS landscape pattern would be similar to the general mosaic patterns of the native (HRV) regime. However, because of alterations

[10] Driving variables are variables that can be correlated with the largest amount of difference in conditions or outcomes.

of biophysical templates, reduction of risk of wildfire in the wildland interface, provisions for human access, and production of human commodities and amenities there are many landscapes where the components of vegetation composition and structure, and succession/disturbance regimes may differ from the native regime and yet result in trends toward equilibrium. The differences are deliberate choices that compensate for alterations in the biophysical template, subsidize "lost" elements or functions at larger scales, or change the process to provide for human use, while trending to dynamic equilibrium.

The eight PVG succession/disturbance regime variables were chosen because they provide a more sensitive indicator than the landscape patterns for what is happening within the carbon-nutrient, food-web and evolutionary systems on different types of enviroments. Succession/disturbance regimes respond relatively quickly to changes in management whereas vegetation patterns change more slowly because of their dependence on changing vegetation composition and structure (for example it takes a long time to grow large shade-intolerant trees in the dry forest or bunchgrasses in the dry shrub, but the type or interval of disturbance can be changed quite rapidly).

Soil disturbance variables were chosen because of their sensitivity to land use, succession/disturbance regimes, and landscape patterns; they indicate risks to long-term soil productivity. Soil disturbance is a measure of the average annual amount of disturbed soil; that is, the amount of soil that is exposed to erosion, displacement, or compaction. The variables are predicted based on the interrelationships of: (1) the amount of different types of disturbance (wildfire, prescribed fire, timber harvest, timber thinning, exotic plant invasion, large herbivore grazing, and range improvements), (2) the type of biophysical environment (PVG), (3) the kind of succession/disturbance regime (type and frequency of disturbance as influenced by vegetation resiliency), and (4) the management prescription models for the scenario. The base values were derived from review of plot data that had measured amounts of bare soil and notes on potential for soil displacement, compaction, or erosion associated with the key types of disturbance.

The base soil disturbance values were stratified by forest and rangeland PVGs, succession/disturbance regimes, and whether the scenario was based on the traditional or ecological management model. The stratification by forest and rangeland PVGs provided sensitivity to the effect of disturbance as well as to resiliency of the vegetation to disturbance. Stratification by the succession/disturbance regimes provided sensitivity to the frequency and severity of disturbance and its interaction with the PVG on resiliency of the vegetation. The stratification to the traditional or ecological management model provided an indicator of the emphasis on mimicking the ecological cause and effect relationships that various soils and vegetation have developed through evolutionary time.

Exotic plant risks variables were chosen because of the major impact exotic plants have had on reductions in native plant diversity and changing succession/disturbance regimes. The CRBSUM modeling of exotics by scenario was only used as a guide in trend of results because of the lack of a current inventory of exotic plants. The key factors used for evaluation of these variables were the prescription emphases for range restoration.

Coarse terrestrial and riparian habitats were chosen because of the importance of a coarse-filter approach in balancing rare species recovery within the ecological management model. In other words, the coarse-filter evaluation emphasizes how well a given scenario achieves recovery of a native pattern of habitats and associated disturbance processes. In comparison, fine-filter analyses evaluate habitat outcomes in respect to population persistence. Both are equally important. For instance, a combined approach may identify that habitat patterns required for recovery of a population are not consistent with the native regimes on BLM- and FS-administered lands. If recovery is desired on BLM- and FS-administered lands the information

can be used to ecologically subsidize the cause-and-effect relationships to produce suitable habitat patterns. In additon, to sustain populations over time in a limited habitat area, populations may need to be subsidized.

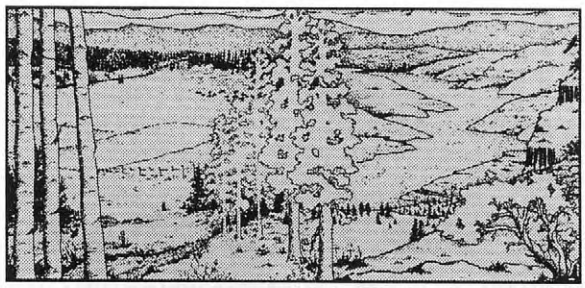
Fire risks within the rural/wildland interface were chosen because of the desire to reduce risks to human dwellings as part of the human component of PFS. The response was based on the modeled scenario prescription mapping, and information on fuels and crown fire risks in forests and woodlands.

Desired human commodity and amenity values were chosen as direct indicators of the human system. These variables also provided a valuable comparison of the effects of the traditional models in the consumptive demand and passive scenarios to the ecological model in the active management scenario.

The summary assessment of relative differences between trends of all variables was based on the cumulative transition to PFS. We emphasize that this is focused on the interrelationships and landscape transitions, not on each variable as a separate entity. For instance forest landscape pattern transitions are also linked to trends of forest PVG succession/disturbance regimes, forest soil disturbance, forest exotic plant risk reduction, wildland and urban- or rural-dwelling interface risk reduction, and human commodity and amenity values, as well as linkages to range patterns and forest-range patterns and their associated variables.

There were four key steps to our analysis of PFS. First, we identified the driving variables that were hypothesized to account for disequilibrium landscape relationships between or within the human, hydrologic, carbon-nutrient, food web, and evolutionary systems. These variables were then summarized for each subbasin, adjacent subbasins, province or ERU, and the Basin.

Second, we reviewed our results to identify the dominant element, function, or process for the selected variables. This provided a view of the changes from the native (HRV) regime through the early historical, recent historical, and current period for each subbasin. This information was summarized to the EIS management region and Basin scales.



Third, we reviewed the active, passive, and consumptive demand scenarios and prescription strategies (appendix 3-M). This provided us with an understanding of the spatial and temporal relationships of the types of management that were assumed to occur for each scenario for each subbasin.

Fourth, we quantified scenario responses (appendix 3-M), for the selected variables by short-term (1st decade) and long-term (50 to 100 year) futures. This provided us with an understanding of the future outcomes for the driving variables for each scenario for each subbasin. This information was summarized to the EIS management region and Basin scales for interpretation of transition rates and trends to PFS.

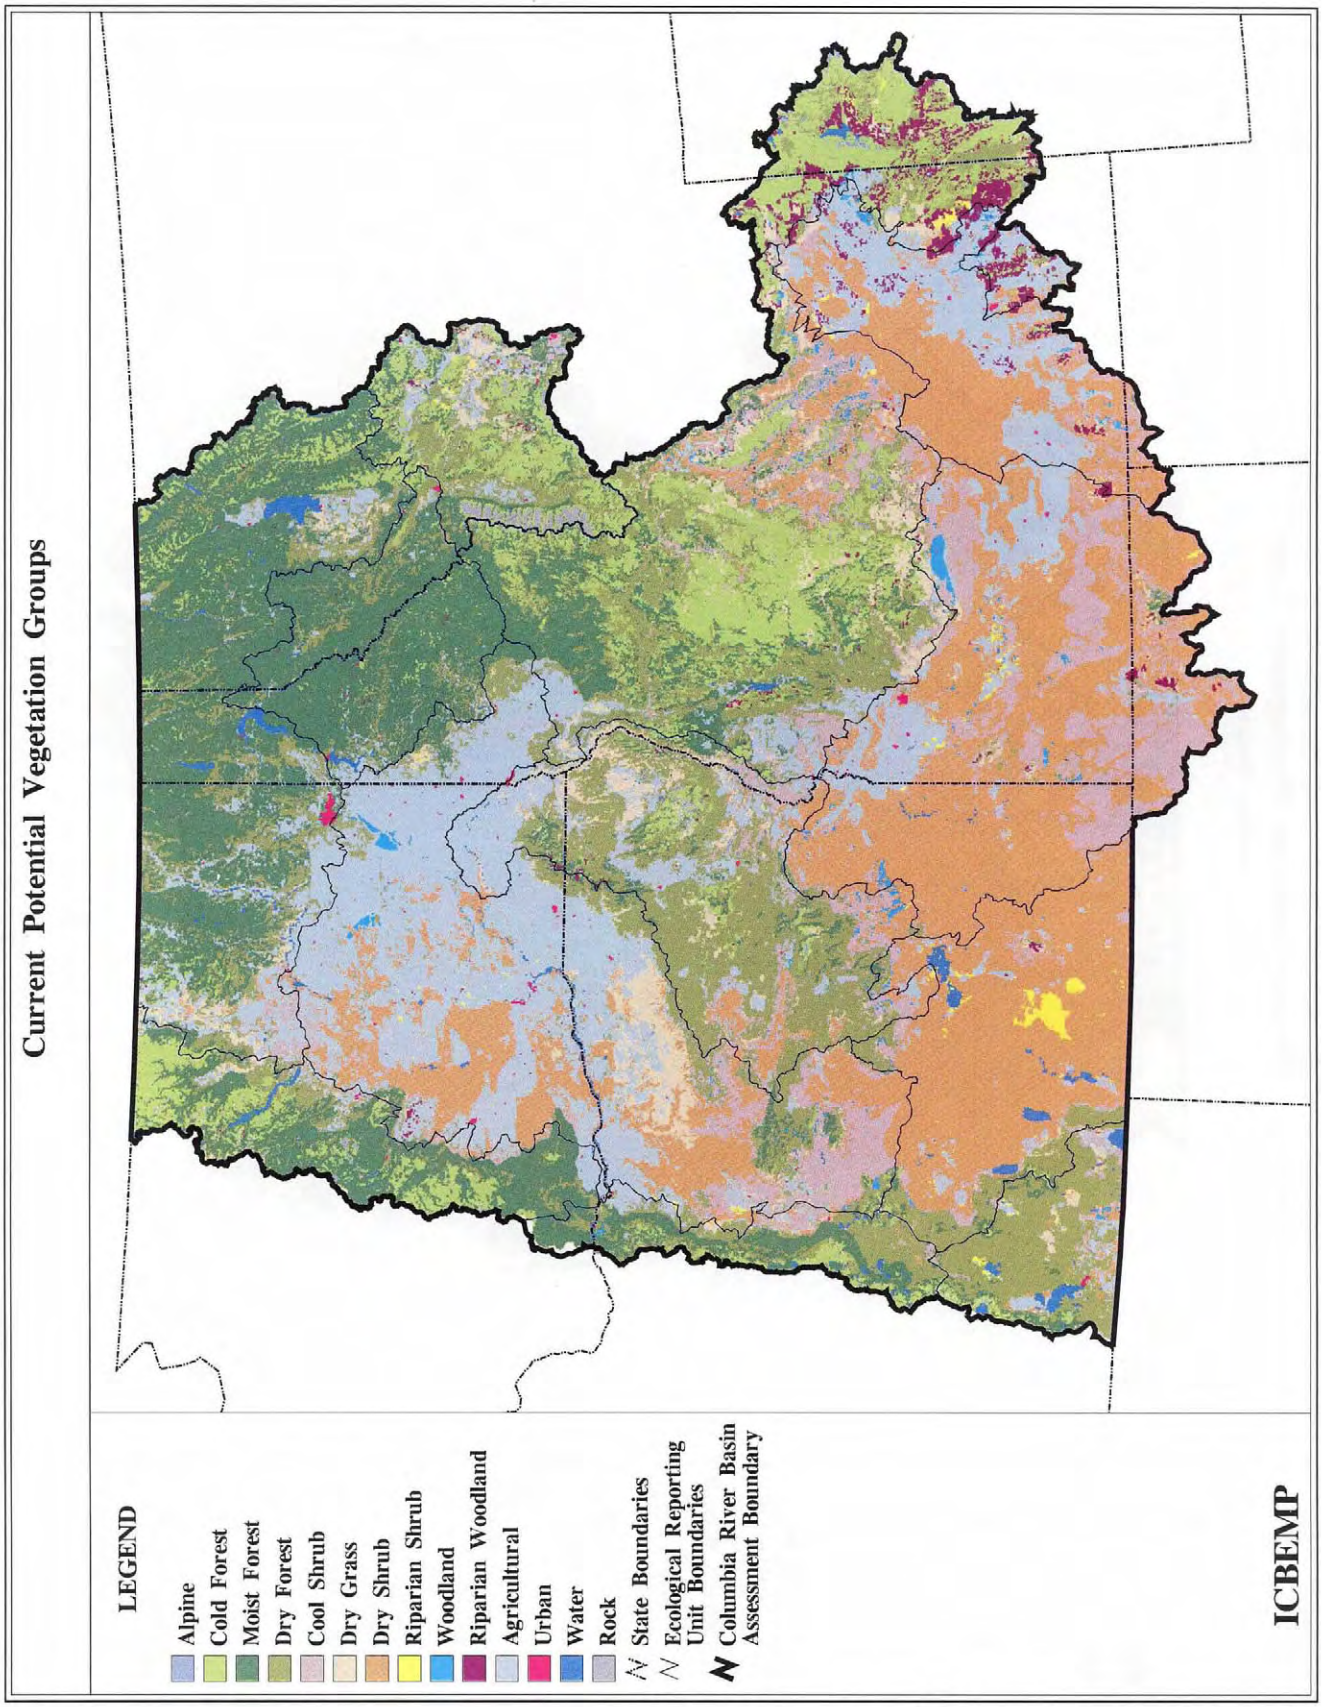
OVERVIEW OF RESULTS

The results and discussion section of this assessment chapter provides a synthesis of regional and landscape patterns of composition, structure, processes, and conditions in the Basin. Prior to discussing the changes in potential vegetation groups, vegetation, disturbance, and regional and landscape patterns, attention is drawn to maps that depict broad-scale vegetation changes and land use. These maps provide an overall context of the Basin, and may be helpful to the reader prior to reviewing the results. The historical and current period PVG maps (maps 3.11 and 3.12) provide a reference for the major changes in site potentials and development of agriculture. Dominant physiognomic type[1] maps (maps 3.13 and 3.14) provide a comparison between historical physiognomic types and current physiognomic types that are dominant at the subwatershed level. Changes in terrestrial community types are depicted in the historical and current period terrestrial community maps (maps 3.15 and 3.16).



Biophysical Template

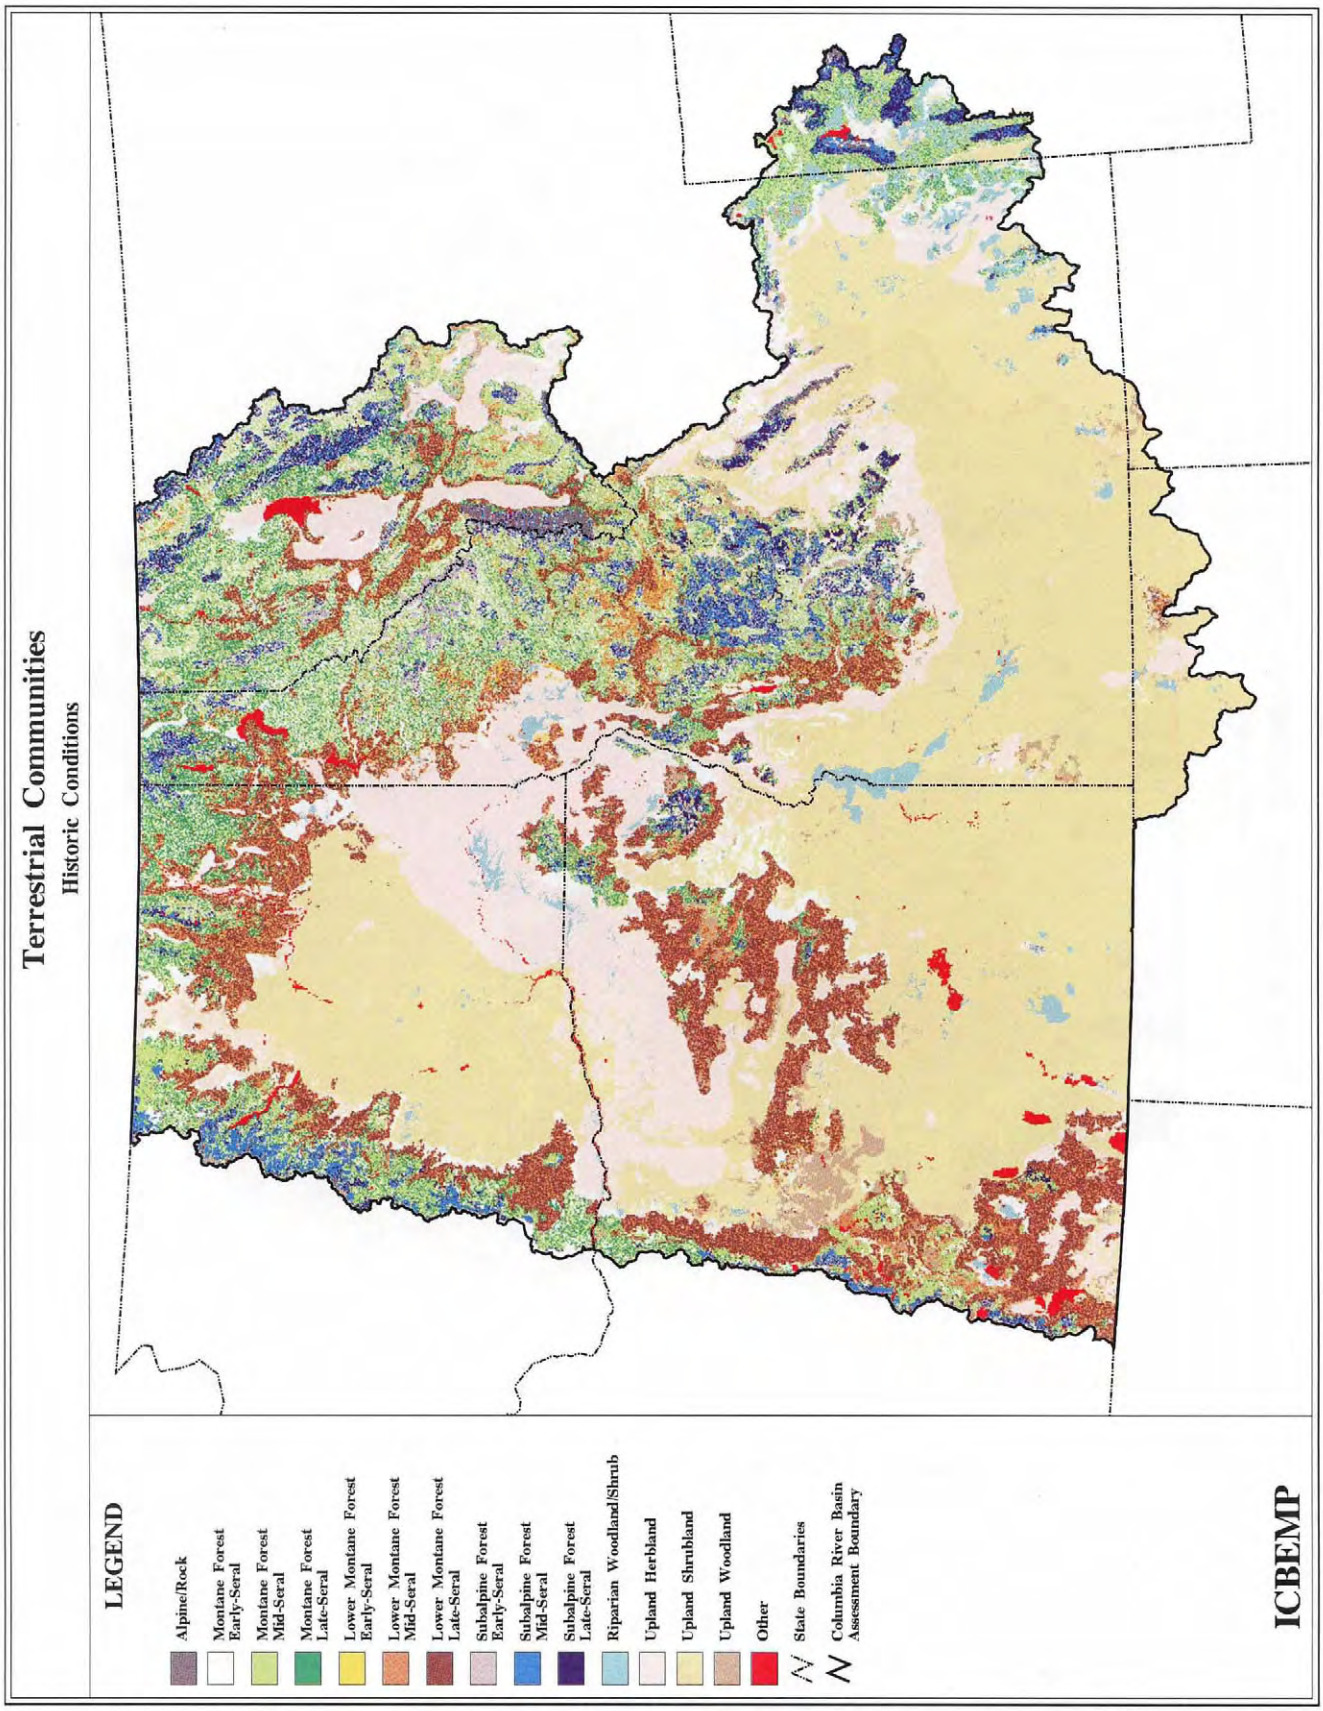
The biophysical templates, and their associated succession and disturbance regimes, changed considerably since the settlement of the Basin by immigrants from Europe and other countries. The associated development of agriculture, mining, urban areas, transportation networks, and hydrologic projects directly altered the biophysical templates. Indirectly, these immigrants also changed the biophysical templates as a consequence of fire suppression; forest management; livestock management; the introduction of exotic (non-native) plants and pathogens; and the decline of soil productivity as a result of erosion, compaction, or nutrient depletion (table 3.17). Consequently, agricultural and industrial development of the Basin created a new set of disturbance regimes and succession pathways with which native species had not co-developed.

The development of agricultural croplands, urban areas, and roads were extensive on "Other" lands (lands other than those administered by the Bureau of Land Management or the Forest Service) relative to BLM- and FS-administered lands (BLM/FS lands) within the Basin (table 3.18). Virtually no conversions to agriculture and urban PVGs occurred on BLM/FS lands. The areal extent of roads (table 3.19) was estimated from an extrapolation of subsample areas. Consequently, the estimates were only indicative of the broad-scale trends of road development; absolute values should not be taken at their face value. Approximately 2 percent of the Basin (both BLM/FS and Other lands) occurred as a road PVG during the current period. Most roads on BLM/FS lands were located in non-wilderness forested areas, and to a lesser extent, in non-wilderness rangeland areas.

[1] Physiognomic type is also referred to as "structure group" in other chapters of this document.

Map 3.11—Historical (circa 1850-1900) period potential vegetation groups (PVGs). PVGs reflect the vegetation potentials (without disturbance) in relation to climate and other physical characteristics. This map represents average conditions at the time of Euro-American settlement.

Map 3.12—Current period potential vegetation groups (PVGs). PVGs reflect the vegetation potentials (without disturbance) in relation to climate and other physical characteristics. This map represents average current period (circa 1990) potentials.



Map 3.13—Historical (circa 1850-1900) dominant physiognomic groups (sometimes referred to as structural groups). Physiognomic groups are aggregations of cover types and structures into similar broad vegetation communities. This map represents average conditions at the time of Euro-American settlement.

Map 3.14—Current period dominant physiognomic types (sometimes referred to as structure groups). Physiognomic types are aggregations of cover types and structures into similar broad vegetation communities. This map represents average current period (circa 1990) conditions.

Land Ownership Group	Percent of Ownership Area in Roads
BLM/FS	1.7
Other	2.1
All	1.9

On Other lands, the most substantial change between the historical and current periods was the conversion of approximately 37 percent of the area from native PVTs to agricultural PVTs. Agricultural cropland, pasture, and hayland, were generally dominated by exotic plants. Most of the agricultural development occurred in the dry shrub (nearly 5 million ha), dry grass (nearly 3 million ha), riparian shrub (nearly 1 million ha), and cool shrub (nearly 1 million ha) PVGs. The conversion to urban areas was less than 1 percent, and was not considered to represent a major broad-scale change. However, urban areas, as classified in this assessment, included incorporated towns and cities having high densities of houses, businesses, industrial parks, roads, and associated developments, and not rural areas such as farms, housing developments, gravel pits, and associated developments. Most roads on Other lands occurred in agricultural and forested areas, with lesser amounts on rangeland areas.

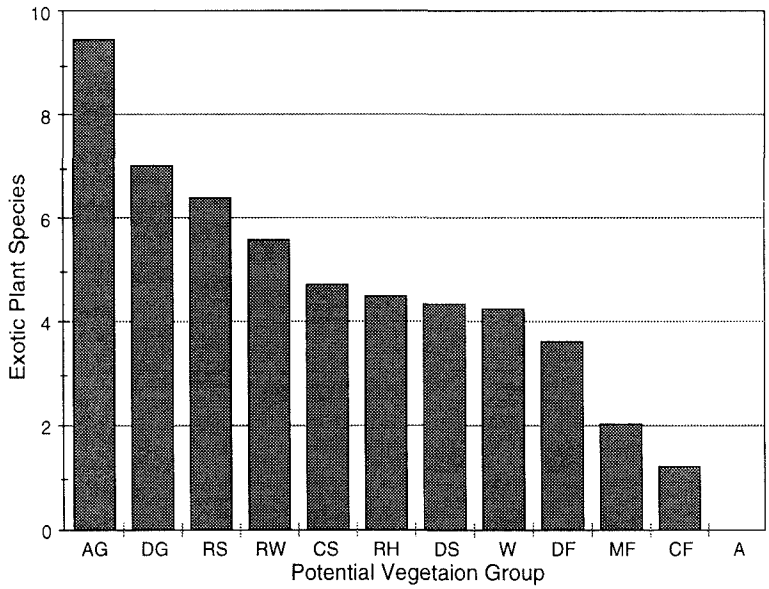

Figure 3.14—This figure shows the average number of exotic plant species [out of 25 exotic plant species (24 legally-declared noxious weeds, plus cheatgrass) assessed in Karl and others (1995)] to which PVGs in the Basin are of high susceptibility to invasion. Our interpretation is that if a PVG is of high susceptibility to invasion by a greater number of species, its potential for invasion by additional exotic plants is greater. This provides only an approximation of a PVG's susceptibility to invasion by exotic plants. PVG acronyms are: AG = agricultural; DG = dry grass; RS = riparian shrub; RW = riparian woodland; CS = cool shrub; RH = riparian herb; DS = dry shrub; W = woodland; DF = dry forest; MF = moist forest; CF = cold forest; and A = alpine. The alpine PVG appears as zero because it is not of high susceptibility to invasion by any of the 25 exotic plant species.

The introduction of exotic plants (for example, annual grasses, and annual, biennial, or perennial forbs) and their establishment in the Basin resulted in the replacement of native cover types and structures, primarily in the dry grass, dry shrub, cool shrub, and riparian PVGs. Although exotic plants invaded the forest PVGs, they typically did not displace the native species to the extent of dominance, partly because exotic plant species were generally shade-intolerant. The establishment of exotic plants in forest PVGs was often dependent upon ample sunlight and was usually associated with roadsides and gaps in forest vegetation. In general, rangeland PVGs on BLM/FS lands including dry grass, riparian shrub, riparian woodland, cool shrub, riparian herb, dry shrub, and woodland (in that order), had a greater potential to be invaded by exotic plants, compared with the forest PVGs (fig. 3.14). These rangeland PVGs cover roughly 43 percent of the BLM/FS lands, and roughly 31 percent of Other lands. The agricultural PVG had the highest susceptibility to the invasion of exotic plants. In contrast, the alpine PVG had the least potential to be invaded by exotic plants. In the current period, we estimated that exotic vegetation dominated at least 3 percent of BLM/FS rangelands and about 1 percent of Other rangelands.

However, since these estimates were based on 1-square-kilometer resolution, the actual area of exotic plant cover was likely much greater and of similar amounts on BLM/FS and Other rangelands.

White pine blister rust, an introduced pathogen, has modified cover types, structures, and successional pathways within the moist and cold forest PVGs. This exotic rust affected the distribution and dominance of western white pine (*Pinus monticola*) and whitebark pine (*Pinus albicaulis*). Historically, these five-needled pines occurred as dominant cover types or residual overstory trees in early- and mid-seral post-fire environments. However, white pine blister rust substantially altered the successional pathways in at least (1) 50 percent of the moist forest PVG, particularly where western white pine occurred as a dominant or common early-seral species; and (2) 50 percent of the cold forest PVG, particularly where whitebark pine occurred as a dominant species. Approximately 19 percent of BLM/FS lands and 8 percent of Other lands were affected by white pine blister rust within the Basin.

Changes of biophysical templates due to the decline of soil productivity were difficult to assess at the broadscale. Excessive livestock grazing pressure on rangelands in the late-1800s and early-1900s caused extensive soil losses from upland habitats. In valley bottom habitats, the local extirpation of beaver, drainage projects associated with agricultural development, and excessive livestock grazing pressure lowered water tables and reduced the areal extent of riparian shrubland and riparian woodland PVGs. In forest ecosystems, changes of biophysical templates due to soil compaction, soil displacement, or nutrient loss were even more difficult to measure than the changes that occurred in rangeland settings. In general, we were unable to detect changes of biophysical templates that were attributable to declines in productivity. The alteration of soil productivity can only be detected using finer-resolution data.

We modified the VDDT models of those PVTs that changed between the historical and current periods as a result of the alterations expressed above (appendix 3-A; table 3.17). Essentially all of the non-forest PVTs had substantial differences in cover types and/or dominant structural stages due to the invasion of exotic plant species. The VDDT models of forest PVTs that had whitebark pine or western white pine as important components of their cover types or structural stages were also changed as a result of white pine blister rust.

General Patterns of Succession and Disturbance Regimes

Because this assessment was focused on the management of BLM/FS lands, we concentrated our study of succession and disturbance regime patterns on areas dominated by wildland forest and rangeland environments. Consequently, we did not address those areas dominated by agricultural and urban land uses in this discussion. The composition of succession and disturbance regimes appeared to be stratified by landforms and their associated PVTs. The three strata that emerged included: (1) foothill and mountain landforms dominated by forest PVGs, (2) basin and foothill landforms dominated by non-forest (rangeland) PVGs, and (3) foothill and mountain landforms dominated by a mixture of forest and non-forest PVGs. For each strata, we compared the composition of succession and disturbance regimes of the native system (that is, HRV) to those resulting from traditional forestry or livestock management systems, and the management of reserves.

Areas in foothill and mountainous terrain dominated by forest PVGs had consistent patterns of succession/disturbance regimes associated with vegetation patterns (figs. 3.11a, b, and c; table 3.20). The dominant disturbances affecting succession in the native system were wildfire, insects, and disease. Harvest practices, fire exclusion, and road development associated with traditional timber management have created more severe disturbance regimes. Current fire regimes in these areas were generally less frequent and consequently had more severe effects than fires in the native system. Insect and disease infestation was generally more

Table 3.20—Relationships of landforms, succession/disturbance regimes, and vegetation structures within forest landscape mosaics.

Structures and Succession / Disturbance Regime Patterns[1]	Landforms						
	Ridge	Slope	Footslope	Plains/Terrace	Toeslope	Channel zone / Draw	Road

pronounced due to the composition and structure of vegetation created by fire suppression and timber harvest. Traditional reserve or wilderness management generally emphasized a passive approach to management, involving little direct vegetation management and a very conservative prescribed natural fire program. Guidelines for prescribed natural fires typically only allow fires that have been lightning-ignited and that achieve prescription guidelines to burn within the reserve (fires are not to escape the reserve boundary). Because few lightning-caused fires have met prescription guidelines, rarely have fires been allowed to burn, with the exception of very large wilderness areas such as the Selway-Bitterroot or Bob Marshal complexes. Consequently, management patterns for traditional reserve also caused substantial changes in succession/disturbance regimes and the associated physiognomic types and compositions. As with commodity management patterns for traditional timber practices, the disturbances in reserve areas were less frequent, more intense, and had more severe effects than those of the native system. Typically, vegetation composition, structure, and patch diversity declined under both types of management.

Areas in basin and foothill terrain that were dominated by non-forest (or rangeland) PVGs also had consistent succession and disturbance regime patterns associated with patterns of vegetation composition and structure (figs. 3.12a, b, and c; table 3.21). Traditional livestock management, in conjunction with fire suppression and the introduction of exotic plants, resulted in substantial changes in these patterns. As with the forest PVGs, the change in regime commonly included less frequent fires that were more intense than those that occurred in the native system. Even in areas under traditional reserve or semi-primitive strategies of management, the introduction of exotic plants and the exclusion of fire substantially changed the succession/disturbance regime and associated vegetation composition and structures. In both the traditional rangeland management and reserve management systems, fire suppression, introduction of exotic vegetation, and excessive livestock grazing pressure created disturbance regimes that had more severe effects. As a result, the diversity of vegetation and landscape structure and composition tended to decline.

Areas in foothill and mountainous terrain, that had both forest and rangeland PVGs had inherently diverse community structure and patch patterns (figs. 3.13a, b, and c; table 3.22). Furthermore, this type of terrain had many complex ecotonal relationships. Traditional timber management, introduction of blister rust, livestock management, introduction of exotic plants, and fire exclusion, substantially changed the succession/disturbance regimes and associated vegetation structures and composition. Typically, the regime change produced less-frequent disturbances having larger cumulative effects than the native system. Traditional reserve or semi-primitive management in conjunction with fire exclusion, and the introductions of blister rust and exotic plants, also substantially changed the succession/disturbance regime and associated vegetation structures and composition. Again, the disturbances were typically less frequent, more intense, and had more severe cumulative effects than the native system. Generally, vegetation structure, composition, and patch diversity declined under the traditional reserve and traditional forestry type of managements. In the foothill and mountain environments, the effects of traditional timber, livestock, and reserve management were more severe than in either the forest or rangeland systems. Changes in foothill and mountain environments were more substantial because their energy gradients were typically much steeper, their disturbance regimes were more dynamic due to the forest/rangeland mosaic, and species diversity was higher.

Biogeochemical Processes

Simulations of the four indices of biogeochemical processes [net primary productivity (NPP), carbon stress index (CSI), water stress index (WSI), and nutrient availability index (NAI)] were compared between historical and current period conditions for PVGs of the Basin in table 3.23. Changes of biogeochemical processes within a PVG were primarily a consequence of changes in vegetation structure and composition. There were substantial changes in NPP from historical to current periods in a number of PVGs at the Basin scale. At this scale, substantial changes were those that exceeded 1.0 percent of PVGs that exceeded 400,000 hectares. PVGs of less than 400,000 hectares in size, such as the alpine and urban PVGs, could not be adequately assessed at this scale.

Relationships between the four indices (NPP, CSI, WSI, and NAI) and the effects on long-term site productivity are complex and do not have the same response among different PVGs. NPP is primarily influenced by the vegetation community (for example, high leaf surface area usually equals high NPP). In forest PVGs, forest communities dominated by dense or multiple layers of short-needled conifers have the highest NPP. In rangelands, those communities with more layers (for example shrub/herb communities) and higher biomass, commonly have the highest NPP. In contrast WSI and NAI are influenced by two primary variables, the vegetation and the soil, which interact with each other and NPP. CSI is influenced by the interactions of NPP, WSI, and NAI. On moisture limited uplands, the WSI will increase when NPP and growth processes exceed

Table 3.23—Change between historical and current period biogeochemical indices by potential vegetation group (PVG).

Current PVG	Square km	Average NPP[1]	Average CSI[2]	Average WSI[3]	Average NAI[4]

[1]Net Primary Productivity (g C m^{-2}).

[2]Carbon Stress Index (index between 0 and 100).

[3]Water Stress Index (index between 0 and 100).

[4]Nutrient Availability Index (g C m^{-2}).

the availability of water. When the NPP and growth processes exceed the availability of water or nutrients in moisture or nutrient limited environments the CSI will increase. The NAI is influenced by the amount of nutrients in the vegetation and the availability in the soil.

Traditional management activities can directly effect the soil by lowering its long-term productivity, this is particularly true for activities that increase rates of erosion and cause compaction or displacement, which alter the native structure of the soil. These effects reduce water and nutrient storage capacity, as well as changing plant-root relationships to the soil structure. We found that these effects occur at a fine scale, and extensively across traditional commodity landscape patterns; we found a correlation between these effects and amounts of timber harvest, excessive livestock grazing pressure, and roads. However, effects were highly variable depending on the amounts and type of activities, as well as the influence of traditional mitigation and protection measures.

The primary indirect effects of management activities that present a risk to long-term soil productivity include the exclusion of fire, invasion of exotics, and the associated development of vegetation communities on soils that are incapable of supporting increased amounts of accumulated biomass. These communities often develop carbon or water stresses, and are very vulnerable to wildfire. Nutrients are bound up in the woody tissues and are subject to volatization from severe wildfires. Thus, a decline in long-term soil productivity may result. We found that these conditions typically occur in the broad transition zones from non-forest to woodland or forest, and present an equal risk as those attributed to traditional commodity activities. Forested landscapes with high CSI or WSI, and low NAI, are also at risk of severe wildfires that can result in erosion and decline in long-term soil productivity.

Within the agricultural PVG, the NPP, CSI, and WSI increased considerably, whereas the NAI decreased substantially. Consequently, risks of stress, insect, and disease mortality decreased as a result of inputs of water, fertilizer, and pesticides. Areas where little could be done with water, fertilizer, and pesticides to change basic energy and nutrient relationships were considered to be wildlands. In wildland settings, biogeochemical processes were predominantly influenced by soil productivity and vegetation composition and structure. In most wildlands, NPP declined slightly, carbon stress increased substantially, water stress increased slightly, and nutrient availability declined substantially. Consequently, current wildlands tended to be less productive, more susceptible to stress, insects, disease, and fire-related mortality, and to decline in long-term site productivity relative to the historical period.

All of the shrub PVGs (that is, riparian shrub, cool shrub, and dry shrub) decreased in NPP, but for different reasons. NPP in the riparian shrub PVG decreased due to declining shrub leaf area as a result of livestock grazing during the growing season. The NPP of the cool shrub PVG decreased in response to the increase of shrub density and tree cover, which was a result of fire exclusion. Increased stocking levels of shrubs and trees resulted in higher competition for limited nutrients. In the dry shrub PVG, NPP decreased in response to an increased abundance of exotic annual grasses that had lower LAIs, and to an increase of woodland tree cover that resulted in higher competition for limited water and nutrients. There was also a decline in NPP in the dry grass PVG due to changes similar to those observed in the dry shrub PVG.

The cool shrub, dry shrub, riparian shrub, and dry grass PVGs all had higher carbon stress levels in the current period as compared to historical conditions, primarily as a result of succession to woodlands. Water stress did not change in the cool shrub or dry shrub PVGs, and increased a small amount in the dry grass and riparian shrub PVGs. Nutrient availability declined substantially in the cool shrub, dry shrub, riparian shrub, and dry grass PVGs in response to (1) increases in woodland extent and the associated tie up of nutrients in the woody tissues and litter, and (2) the loss of

nutrients from exotic annual grass systems due to erosion and increased volatilization from shorter fire-return intervals. Soils that developed in shrub- and grassland-maintained systems and that changed with succession to woodlands had the highest risk of decline in long-term site productivity. This was due to the fact that carbon and nutrients were stored in the wood, rather than in the soil, and soil nutrients often declined due to erosion. When woodlands experienced high-intensity wildfire conditions, there were high risks of nutrient capital losses through volatilization or erosion. Riparian shrub communities were also subject to long-term decreases in productivity and increases in stress as a consequence of soil compaction and a decline in water availability, due to lowered water tables when adjacent stream channels were incised.

NPP in the woodland and riparian woodland PVGs increased in response to increasing amounts and densities of woody vegetation. The increase of NPP appears to result from the increase of scattered-to-dense tree vegetation relative to shrubs and herbs in these areas, which was caused by fire exclusion and excessive livestock grazing pressure. Carbon stress levels decreased and water stress increased slightly in the woodland and riparian woodland PVGs because of the decrease in total biomass of trees, shrubs, and grasses. An increased water use by trees resulted from a more simplified patch structure as these communities became dominated by a dense, continuous, upper-canopy woodland layer and lost their herb and shrub layers. Nutrient availability increased substantially in these types in response to the loss of the herb and shrub layers, but this lack of herb cover also subjected these types to erosion.

This increased response in the woodland PVGs is opposite to the decline exhibited in the shrub and grass PVGs. Both have increased amounts of woody material, which can tie up nutrients and make them less available. However, the increase in NPP and soil temperature in the woodland PVGs, which was the result of a shift to mid-seral forest and shrubland dominance, caused an increase in nutrient capture and decay rates. These increased rates have, in turn, resulted in increased nutrient availability. However, because of the lack of light, and high competition for moisture within the woodland and shrub types, understory herb production is low. Consequently, most of the nutrients that are available are not used for growth.

NPP in the dry and cold forest PVGs increased in response to the conversion of historical forests dominated by shade-intolerant tree species to current-period forests dominated by shade-tolerant tree species. Shade-intolerant tree species generally have longer needles that are arranged in an open configuration, as compared to shade-tolerant species that typically have a short, dense, two-ranked, needle arrangement. The higher photosynthetic surface area of the shade-tolerant species results in higher productivity unless levels of CSI, WSI, or NAI restrict NPP. Increased densities in forests of shade-tolerant species has resulted in higher NPP for these two PVGs.

This increased dominance by shade-tolerant species occurred in the dry forest PVG as a result of traditional tree harvest practices, tree regeneration practices, and fire exclusion. Although traditional harvest and regeneration practices favored shade-intolerant tree species on some managed patches, when combined with fire exclusion, these practices favored shade-tolerant species at landscape and regional scales. The increased dominance by shade-tolerant species in the cold forest PVG occurred as a result of fire exclusion and blister rust mortality of whitebark pine with a shift to subalpine fir.

In contrast to the dry and cold forest PVGs, NPP in the moist forest PVG declined for two primary reasons: (1) blister rust-caused loss of western white pine, a fast-growing dominant species having high productivity; and (2) the general conversion from structurally complex forested landscapes to simplified landscapes as a result of traditional harvest practices and fire exclusion. Instead of shifting to higher densities of multiple-layer forests and tree species with higher LAI, the shift was to a dense forest of trees species with lower LAI.

Carbon and water stress did not change substantially in the moist forest PVG, but nutrient availability declined considerably. The decline of nutrient availability occurred primarily as a result of nutrients being tied up in litter and live and dead wood, as a consequence of fire exclusion; and the lack of mixed and non-lethal fires that maintained more open-stand conditions and reduced litter accumulation. Carbon stress declined and nutrient availability increased in the cold forest PVG, with no change in water stress. These trends were attributed to an increase of early-seral communities that had less carbon and nutrients stored in live or dead wood and litter. The dry forest had substantial increases in carbon and water stress, and a considerable decline in nutrient availability. In association with the higher NPP driven by the increase of shade-tolerant species, the dry forest PVG was highly stressed and more susceptible to stress-, insect-, disease-, and fire-related mortalities, and risks of declining long-term site productivity.

The biogeochemical relationships on BLM/FS lands were very similar to the responses across the Basin as a whole. The primary difference was the lack of agriculturally influenced biogeochemical processes on BLM/FS lands. There were substantial differences within BLM/FS lands, specifically between areas that had been historically managed using traditional timber harvesting and livestock grazing practices, as compared to areas that had been managed for wilderness and semi-primitive conditions. Areas of wilderness and semi-primitive conditions that were relatively small and where fire exclusion had been successful, generally had lower NPP, higher carbon stress and water stress, and lower nutrient availability. Areas of wilderness and semi-primitive conditions that were moderate to large in size, where fire exclusion had generally not been successful, generally had higher NPP, lower carbon and water stress, and higher nutrient availability.

Relationships to Succession/ Disturbance Regimes

Changes in succession and disturbance regimes were directly related to biogeochemical processes and associated topographic diversity, contagion of vegetation patches, drought frequency, and fire occurrence probability. Although, potential vegetation types were directly associated with biogeochemical processes, they were not well correlated with succession/disturbance regimes at the landscape or regional scales. PVTs occurred in a wide variety of compensating environments and responded to different variables than those that drove succession/disturbance regimes.

The general relationships among biogeochemical processes, the landscape mosaic, and succession/disturbance regimes are summarized in table 3.24. Cycling regimes were typically found in areas where NPP was relatively high and decay rates (as indicated by the NAI) were low to moderate. This relationship between NPP and NAI allowed the accumulation of dead wood and litter, or the development of carbon or water stresses to reach levels that produced a cycling regime in conjunction with a disturbance agent (such as fire, insects, disease, or wind). The accelerated-cycling regime generally had periodic low intensity disturbances that thinned the mature vegetation. Consequently, the accelerated-cycling regime had high productivity and nutrient availability, whereas carbon and water stresses were low to moderate. However, because of the topographic position, contagion to other succession/disturbance regimes, or probability of infrequent but severe droughts, the accelerated-cycling regime eventually experienced disturbance events that cycled. The retrogressive-cycling regime had low productivity because site vegetation was highly stressed by carbon or water availabilities, or was subject to physical impacts from insects, disease, or livestock during the growing season.

Table 3.24—Relationships among biogeochemical processes, succession/disturbance regimes, and the landscape mosaic.

Succession/ Disturbance Regime	Code	NPP[1]	CSI[2]	WSI[3]	NAI[4]	Landscape Mosaic Relationships[5]
Frequent Maintenance	FM	M[6]	L	M	H	Typically in areas with relatively high fire-occurrence probability.
Irregular Maintenance	IM	H	H	L	M	Typically in footslope areas with subsoil water.
Less Frequent Maintenance	GM	M	M	L	M	Typically in colder zones with lower probabilities of drought and fire occurrence.
Accelerated Cycle	AC	H	L	M	H	Typically on upland forest or shrub slopes.
Retrogressive Cycle	RC	L	L-M	L-H	M	Typically a combination of physical impacts on plants, such as herbivory, or high carbon or water stress.
Short Cycle	SC	L	L	L	M	Commonly in river/stream channel, earth flow, or avalanche zones.
Moderate Cycle	MC	H	L	H	M	Commonly on upland forest and non-forest types.
Long Cycle	LC	H	H	M	M	Commonly on upland forest and non-forest types.
Very Long Cycle	VC	H	M	L	L	Typically in valleys or wet areas with low fire-occurrence probability and long intervals between drought.

[6]L = Low; M = Moderate; H = High.

The maintenance regime generally had moderate productivity and high nutrient availability (table 3.24). These systems had decay rates and disturbance intervals that prohibited substantial accumulation of dead wood and litter, and maintained high vigor of the dominant vegetation. Consequently, when disturbance events occurred, the structure and composition of the dominant vegetation did not measurably change. The difference between areas with frequent- versus infrequent-disturbance events was typically related to either climate or the probability of a disturbance event. Colder climates tended to have less dead wood and litter accumulation during a given period of time and lower levels of stress. Consequently, even with a high probability of disturbance occurrence, there may not have been enough dead wood and litter, or stress to provide the conditions suitable for a frequent-maintenance regime. The irregular-maintenance regime typically occurred in a landscape mosaic position where disturbances occurred, but the available subsoil water reduced the severity of those disturbances.

Biogeochemical Assessment Limitations

Our assessment of broad-scale biogeochemical processes had many limitations associated with scale. The scale of our vegetation layers did not always correspond to the scale of the ecophysiological parameters, soils layers, or a digital elevation model. As a result, it was difficult to obtain agreement among spatial locations across all data layers. It was also difficult to develop parameters of the ecophysiological file that corresponded with the vegetation and site layers. Therefore, some fringe areas in the range of a species or lifeform were not modeled with high accuracy. However, we believe that areas representing modal conditions of a particular ecosystem were simulated adequately with the BGC model.

It was especially difficult to mesh the independently-created weather data layers with vegetation data layers and obtain complete correspondence. There were groups of pixels where climate and soils would not support the vegetation depicted in the cover type and structural stage data layers. In these instances, the lack of correspondence between the ecophysiological file and the weather and/or soil data layers could result in negative NPP values. For example, a negative NPP value was produced for the zone between lodgepole pine *(Pinus contorta)* and sagebrush shrublands. The weather data for the lodgepole pine stands was more typical of sagebrush shrublands, which falsely indicated that there was not enough water available to support trees. However, ecophysiological parameters for lodgepole pine forests were used in the BGC model resulting in negative productivity values. Consequently, we set all negative values of NPP to 1.0.

Another serious scale limitation of our application of the BGC model was that each unique combination of cover type and structural stage was assigned a single leaf-area-index (LAI) value based on average values derived from the 1991 Advanced Very High Resolution Radiometer satellite image. Because cover types and structural stages were coarse, we expected the distribution of LAI values to be similar to the average value for each combination. That is, the lower range of the LAI distribution would most likely occur on the more water- or temperature-stressed ranges of the cover type/structural stage combination, and higher LAI values would likely occur on the wetter and warmer sites. As a result, these simulations most likely overestimated stress on the poorest sites (for example, dry sites with artificially high LAI) and underestimated productivity on the best sites (for example, high NPP with a very low LAI). These limitations can be addressed using more sophisticated land cover and structural stage classifications, a more detailed representation of the ecological parameters, and perhaps most effectively, through iterative model simulations that would allow some degree of equilibration between weather, soils, and vegetation input values.

Another limitation of our simulations was the problem of meshing the 2-square-kilometer BGC-model output to other 1-square-kilometer data layers. The composition of the four, 1-square-kilometer pixels comprising a 2-square-kilometer pixel could be quite diverse, especially if they occurred on the edges of a landscape element. This was an unavoidable consequence of using a sophisticated biogeochemical process model to evaluate a region as large as the Basin.

Summary

The relationships between biogeochemical processes and broad-scale vegetation are summarized as follows:

Net Primary Productivity (NPP)

1. Shade-intolerant forests had lower NPP than shade-tolerant forests, probably because of lower leaf areas and higher stem respiration costs.
2. Early-seral forests had higher NPP than late-seral forests and mid-seral forests, and varied in NPP depending on site relationships, composition, and structure.

3. Riparian communities were much more productive than upland sites.
4. Plant communities dominated by exotic species had low structural and species diversity resulting in lower NPP.
5. Productivity across PVGs followed conventional wisdom, with the least NPP values in the driest or coldest ranges of a biome, and values increasing as moisture or temperature increased.
6. Conversion of native grasslands and shrublands to agriculture generally increased NPP, but that increase was mainly due to fertilization and irrigation influences on the high leaf areas of agricultural crops.

Carbon Stress Index (CSI)

1. The PVGs with the highest carbon stress occurred in the driest areas. The productive moist forests had some of the lowest CSI values, indicating less stress.
2. Shade-intolerant forests had higher carbon stress than shade-tolerant forests, because shade-tolerant forests had lower live stem tissue respiration.
3. Single-layer late-seral forests had lower carbon-stress values than multi-layer forests, particularly on dry sites.
4. Upland shrublands and herblands had higher CSI values than riparian sites.

Water Stress Index (WSI)

1. Water stress usually increased with successional status. An increased water availability in early-seral communities was probably due to the lower leaf areas.
2. Although riparian environments have high water availability, they also have high water stress during the summer drought period and are highly sensitive to activities that lower the water table.

Long-term Site Productivity, Nutrient Availability Index (NAI)

1. In general, nutrients were more available in early- to mid-seral forest settings.
2. Single-layer late-seral forests had higher rates of decomposition than multi-layer forests. This is because more sunlight and subsequent warmer temperatures reach the forest soil surface.
3. Herblands and shrublands had higher rates of nutrient turnover than forests because of warmer temperatures and higher relative amounts of herbaceous vegetation.

Succession/Disturbance Regimes

1. The type of regime (cycle or maintenance) had low correlation with potential vegetation types, but had high correlation with potential vegetation lifeform and regeneration strategies of dominant species.
2. The type of regime had high correlation with various combinations of NPP, CSI, WSI, NAI, and the landscape mosaic.

Regional Trends of Succession/ Disturbance Regimes

The succession/disturbance regimes changed substantially between the historical and current periods (table 3.25). For the Basin as a whole, four succession/disturbance regimes were nearly eliminated between the historical and current periods (that is, the accelerated-cycle, frequent-maintenance, less-frequent maintenance, and irregular-maintenance regimes). To the contrary, two successional/disturbance regimes that did not exist historically were apparent during the current period (retrogressive cycle and very-long cycle regimes). Of the four regimes nearly eliminated, only the active management scenario was forecasted to substantially increase its representation within the Basin in the future. The active management scenario was also effective in reducing the extent of the retrogressive cycle and the very-long cycle regimes. The declining and increasing trends

Table 3.25—Basin distribution (%) of succession/disturbance regimes for historical and current periods, and 100-year projection for management scenarios .

[1] Scenarios: CM = Consumptive Demand Management; AM = Active Management; PM = Passive Management.

of the moderate and short-cycle regimes, respectively, were not measurably altered by any management scenarios. The trends of succession/disturbance regimes upon BLM/FS lands mirrored the trends of the regimes across the Basin as a whole. The future projections of an active management scenario on BLM/FS lands reversed the historical trends, resulting in a level that approximated historical conditions for five of the seven regimes that had departed the most between the historical and current periods (that is, the accelerated-cycle, irregular-maintenance, retrogressive-cycle, short-cycle, and very-long cycle regimes). Neither the consumptive demand nor the passive management scenarios were effective in reversing the historical trends of these, or any other regimes. On the other hand, an active management scenario was projected to result in levels of the less-frequent cycle regime that greatly differed from historical conditions on BLM/FS lands. However, this was a deliberate consequence of extending the disturbance interval in frequent regimes to accumulate biomass and to achieve proper functioning landscapes.

We believe active management scenarios will likely reduce the frequency of maintenance-type disturbances in order to accumulate biomass for timber harvest, livestock grazing, and stream protection. Consequently, the preponderance of the less-frequent maintenance regime will probably greatly exceed its extent during the historical period. When stratified by the two management regions, the historical and projected future trends of succession/disturbance regimes were consistent with the trends observed for the Basin (table 3.26).

During the current period, the areal extent of the long-cycle succession/disturbance regime was approximately two and one-half times its historical level on BLM/FS lands (table 3.25). Neither consumptive demand nor passive management scenarios seemed to be effective in reducing the historical to current trend of the long-cycle regime. Although an active scenario was projected to reverse its historical to current trend substantially, the areal extent of the long-cycle regime would likely still exceed historical levels. Even with an active approach, many forest types would probably be managed for a longer cycle of disturbance so that biomass could accumulate for timber products, stream protection, big game security cover, visuals, and other values deemed important by society.

The moderate-cycle disturbance regime dominated BLM/FS lands during the historical period, but was reduced by more than one-half by the current period (table 3.25). The consumptive demand scenario was not projected to be effective in reversing the historical to current trend of the moderate-cycle regime. The declining trend was expected to continue with active and passive management scenarios, but for different reasons. Under an active scenario, fire would likely be intentionally excluded from some portions of the dry shrub PVG to reduce the potential of invasion by exotic forbs and annual grasses. Consequently, a longer-cycle disturbance regime would result, which in this instance, would promote the shift from exotics to a native species community. The fire-return interval would also be extended under a passive management scenario. However, in this case, an increase in fuels would likely increase the potential for very hot and lethal fires. Lethal fires could, depending on the PVG (for example, the dry shrub), lead to an increase in the composition of exotic forbs and annual grasses. This shift in composition (to exotics) would subsequently reduce the fire-return interval and thus, increase the preponderance of the short-cycle regime.

As stated earlier, the retrogressive cycle did not occur at the regional scale during the historical period. However, during the current period, the retrogressive-cycle regime dominated the Basin, regardless of land ownership strata (table 3.25). The dominance of the retrogressive-cycle regime was largely attributable to stress-, insect-, and disease-induced mortality of trees in forest PVGs; and excessive livestock grazing pressure; fire exclusion; and invasions of exotic plants in the cool shrub, dry shrub, and dry grass PVGs. The consumptive demand and passive management

[1]Scenarios: CD = Consumptive Demand Management; AM = Active Management; PM = Passive Management.

scenarios did not measurably alter the preponderance of the retrogressive cycle. However, the active management scenario essentially eliminated the retrogressive-cycle regime within a 100-year period.

The short-cycle regime was a minor component of the succession/disturbance regimes of all land ownership strata within the Basin during the historical period (table 3.25). During the current period, it was still only a minor component on BLM/FS lands, but it was a dominant succession/disturbance regime on Other lands. The increased areal extent of the short-cycle regime on BLM/FS lands in the current period was largely associated with the invasion of exotic annual grasses, and on Other lands to annual tillage practices on agriculture lands, in addition to the invasion of exotic annual grasses. On BLM/FS lands, the increasing trend that occurred between the historical and current periods would likely continue under the consumptive demand and passive management scenarios, although the increase would be far greater under a consumptive demand approach. On the other hand, an active management approach would reverse the historical trend, resulting in an extent of the short-cycle regime that would approach historical conditions. On Other lands, the areal extent of the short-cycle regime would continue to increase due to an increasing dominance of exotics, regardless of management scenario. The preponderance of the short-cycle regime on Other lands was projected to be the highest under the passive management scenario because livestock grazing was assumed to increase on Other lands as a result of a reduction in grazing within the reserves on BLM/FS lands.

The very-long cycle regime was virtually absent during the historical period (table 3.25). However, its extent increased substantially by the current period, largely as a result of fire exclusion. Only an active management approach seemed to be effective in reducing the areal extent of the very-long cycle regime to a level approximating its historical.

[1]Scenarios: CD = Consumptive Demand Management; AM = Active Management; PM = Passive Management.

We estimated the historical and future trends of insect and pathogen disturbances within forest settings. Tree mortality, resulting from insects and pathogens, affects fire regimes, productivity, habitat suitability, and hydrologic processes. The broad-scale potential of forest insects and diseases has nearly doubled between the historical and current periods for the Basin as a whole, as well as on BLM/FS lands within the Basin (table 3.27). These trends were relatively consistent when the Basin was stratified by the two management regions (that is, EEIS and UCRB). Only the active management scenario effectively reversed the historical trend (potential of insects and diseases) to a level nearer to the historical conditions. The projected level of forest insect and disease potentials under the active management scenario was still relatively high in relation to the historical period. This was because the continued effects of blister rust and the management effects on some forest communities (managed for visuals, big game cover, and watershed protection) would promote relatively high levels of insect and disease disturbances.

We estimated future projections of dominant disturbance activities resulting from consumptive demand, active, and passive management scenarios within forest settings. Average levels for total forest disturbances (that is, wildfire, prescribed fire, thinning, and harvest) on BLM/FS lands were not substantially different between the historical period and projections of the active management and consumptive demand scenarios (table 3.28). However, the activities projected for the passive management scenarios were nearly 30 percent below those of the historical period on BLM/FS lands.

The projections for soil disturbance resulting from vegetation treatments in forest and rangeland settings varied substantially among management scenarios and between the historical and current periods (table 3.29). The amount of soil disturbance during the historical period was approximately 5 percent less than that estimated for the current period on BLM/FS lands. The difference between levels of soil disturbance on Other lands was even more substantial. The projections of soil disturbance were substantially lower for the active

[1] Scenarios: CD = Consumptive Demand Management; AM = Active Management; PM = Passive Management.

and passive management scenarios, relative to a consumptive demand scenario, but all management scenarios had projections substantially higher than the projections for the historical period.

Not surprisingly, the historical and projected future trends of broad-scale physiognomic types (appendix 3-H) were associated with the broad-scale trends of succession/disturbance regimes. There were two primary trends that we believe should be emphasized. In the forests, particularly on BLM/FS lands, the succession of early-seral to mid-seral types, and the retrogression of late-seral to mid-seral types, which we observed between the historical and current periods, were transitions that did not occur in native systems. These transitions were caused by two primary trends. The first trend was the exclusion of fire and extensive harvesting of large, shade-intolerant trees that were more resistant to stress, insects, and diseases. As a result, forest dominance shifted to smaller, shade-tolerant trees that were more susceptible to stress, insects, and diseases. Because fires have been excluded from large areas for an extended period of time, and because harvest practices also affected a relatively large proportion of the Basin, the historical trends will be very difficult to reverse unless management activity levels are greatly increased above traditional levels, or traditional activity levels are concentrated to relatively small geographic areas.

The second primary trend pertains to rangelands, and reflects the exclusion of fire, excessive livestock grazing, and invaion of exotics that shifted (1) herb to shrub, woodland, or exotic, and (2) shrub to woodland. The shift of herb to shrub, from historic to current, was primarily detected within dry shrub and cool shrub PVGs. The shift of herb or shrub to woodland was primarily detected within the cool shrub and dry grass PVGs. The changes in disturbance regimes operated to shift herb to shrub or woodland, or shrub to woodland, resulting in a long-cycle regime. However, when the changes in disturbance regime operated to shift herb to exotics, the result was a short-cycle regime, particularly if the exotics were highly-flammable exotic annual grasses. However, with invasion of exotic perennials or loss of soil the regime shifts to a retrogressive system. Thus, the long cycle, short cycle, and retrogressive regimes have become a common component of shrubland and grassland PVGs and act to either lengthen, shorten, or reverse historical succession/disturbance cycles. The increased prevalence of these regimes was attributable to excessive livestock grazing pressure, fire exclusion, and the invasion of exotic plants. The scenarios in appendix 3-H show that in the future, some reversal of the loss of herb and shrub could occur due to the increased use of fire and exotic plant control in the scenarios, which could cause decline in shrub and woodland. However, shrub would eventually increase as a result of use of fire in woodlands and succession from herb to shrub.

TRENDS IN REGIONAL AND ECOLOGICAL REPORTING UNIT SYSTEM DYNAMICS

The Basin

Vegetation succession in the Basin was typically driven by the growth and development potentials of the biophysical setting (that is, PVTs and PVGs), which in turn, were limited by moisture or temperature. The presence of woodland or forest PVGs generally indicated adequate soil depth and moisture for woody conifer or broadleaf tree regeneration and growth to maturity. These conditions were found in the woodland, dry forest, moist forest, cold forest, and riparian woodland PVGs (table 3.17). The riparian woodland type was generally found in basins, riparian, or wetland sites where subsoil moisture was higher than in other forest types. However, subsoil moisture was also seasonally dry and adequately aerated in riparian woodland areas, so that broadleaf and conifer riparian woodland species could regenerate and grow to maturity.

The presence of rangeland PVGs generally indicated a very dry climate or very shallow soils that were too dry for successful tree regeneration; a very cold climate with growing seasons too short for tree regeneration; or subsoil water tables that were too wet for tree regeneration. These environments were found in the dry grass, dry shrub, cool shrub, alpine, riparian shrub, and riparian herb PVGs. In general, the dry grass and dry shrub types were found at lower elevations and in lower precipitation zones than forest and woodland PVGs. However, the dry grass type was typically found in greater precipitation zones (> 30 cm/year) than the dry shrub type (< 30 cm/year).

Within the woodland and dry forest PVGs, the dry grass and dry shrub types were often found as inclusions on shallow or rocky soils. The dry grass PVG is typically found in areas of lower elevation, on the western edge of the Rocky Mountains, where winter and spring conditions are cloudy and relatively mild (Daubenmire 1970). This PVG is also found in areas with shallow soils over bedrock, and in areas on the eastern edge of the Basin with a predominance of summer precipitation (that is, a shift to continental climate). The cool shrub PVG was typically found at higher elevations in dry climate zones or mixed with the dry or cold forest PVGs on shallow or rocky soils. The alpine PVG was typically found from 2,150 to 3,700 meters elevation. Riparian shrub and riparian herb PVGs were typically found in areas where subsoil moisture was wet throughout the growing season, or at least during the spring and summer. Riparian herb types were often found where the subsoil water was stagnant and poorly aerated.

The other non-anthropogenic PVGs include water and rock. In this assessment, we did not differentiate between native large bodies of water and reservoirs created by dams, so there was generally no difference in the data between historical and current periods. However, we believe that recent-historical water projects substantially changed the areal extent of the water PVG, and that a more detailed examination is needed to identify where and to what extent the water PVG has changed.

The rock PVG generally occurred within large areas of cliffs and mountaintops, but could also have included some borrow pits and mines. The areal extent of the rock PVG did not change between historical and current periods. However, we believe that more rock and gravel areas have developed in borrow pits, mines, and industrial areas. In more detailed assessments, the rock PVG should be disaggregated into native and anthropogenic types, and then evaluated for change. Water and rock environments do have succession and disturbance relationships, but they were not addressed in this assessment. The anthropogenic PVGs included urban, agricultural, and road types. There are succession and disturbance relationships within urban and agricultural types, but they too were not addressed in this assessment due to our emphasis on the management of BLM/FS ownerships and on other wildlands (for example, forest, rangeland, and riparian). The road PVG was addressed at a very coarse scale in this assessment.

Woodland PVG

Most (70%) of the woodland PVG occurred above 1,200 meters elevation; 30 percent occurred below 1,200 meters elevation (table 3.18). The woodland PVG is a relatively rare type in the Basin, comprising no more than 1 percent of the region. Although there was a relatively high amount of woodland cover types and structures in the Basin during the current period, most had encroached into the cool shrub and dry grass PVGs. Encroachment of the woodland cover types and structures onto these PVGs was primarily a function of two types of events: (1) fire suppression that allowed woody species to survive, and (2) excessive livestock grazing pressure that decreased the competition from herbaceous species. Approximately 50 percent of the woodland PVG occurred on BLM/FS lands (maps 3.11 and 3.12).

The woodland PVG is typically located on edges of mesas, ridges, and knolls where fractured bedrock is near the surface and soil depths are shallow. The restriction of woodlands to these sites has been attributed to fire exclusion (Burkhardt and Tisdale 1976). These sites generally have low soil water availability due to shallow soils. Consequently, herbaceous production is low. The woodland PVG is often found in the driest of the zones that would support conifer or broadleaf tree regeneration and growth to maturity. There has essentially been no historical to current period loss of the woodland PVG; the rocky sites that the woodland PVG occupies were not typically developed for agriculture or urban uses.

Woodland tree regeneration was generally low throughout the Basin, but adequate for replacement of relatively open-growing, mature trees. In the native system, the abundance of upland herb and shrub structures remained relatively stable (about 70% of the woodland PVG) but varied somewhat depending on the length of fire-return intervals. The composition of early-seral, mid-seral, and late-seral structural stages also remained relatively stable at approximately 5, 15, and 5 percent of the woodland PVG, respectively.

The native fire interval was variable depending on the site production of fine fuels and conductivity of those fuels. Fire-return intervals ranged from 5 to 150 years. Approximately 40 percent of the fires were non-lethal and maintained grassland, shrubland, or late-seral single-layer woodland types on the less rocky soils. Thirty percent of fires were mixed regimes that maintained a mosaic of open grass and shrub structures intermingled with patches of woodland. Another 30 percent of fires were generally lethal crown fires that varied in frequency from 20 to 150 years. The mid-seral woodlands probably occurred on ecotone areas that had varying fire regimes, depending on drought and fire cycles. Some areas did not burn because of topographic location, or occurred on very rocky sites that lacked ignition fuels. The fire season was relatively long in this type; it generally began in May and lasted into October.

The dominant change that we detected between the historical and current periods within the woodland PVG was the loss of the upland herbland physiognomic type due to fire suppression (table

3.30). Most (70%) of the PVG was dominated by shrubland types during the current period. The mid-seral woodland physiognomic type increased to approximately 30 percent of the PVG. In the current period, we detected virtually no early-seral or late-seral physiognomic types. We suspected that due to the suppression of underburning fires the older, larger trees of the late-seral stages were dying of drought stress or insect attacks, a consequence of stress induced by dense understories of tree regeneration. Exotic plants did not dominate the woodland PVG but could be found as understory dominants in areas having disturbed soils, especially on sites with a history of excessive livestock grazing pressure. We computed a 58 percent and 85 percent similarity of physiognomic type composition between historic and current periods for the Basin as a whole and for BLM/FS lands respectively (table 3.31). Fire regimes generally shifted, with a majority (95%) exhibiting lethal-fire behavior that killed the shrub or tree overstories. The fire-return interval was 75 to 150 years. The similarity of historical and current fire regimes was 47 and 67 percent for the Basin as a whole and BLM/FS lands, respectively (table 3.31).

There was little similarity of historical and current succession/disturbance regimes of the woodland PVG, regardless of land ownership strata (table 3.31). In terms of overall departure of succession and disturbance ratings, the woodland PVG was rated high. Departures were attributed to road and harvest systems, changes in landscape vegetation composition and structure, and changes in the fire regime. Secondary effects were related to the invasion by exotic plants. In general, these changes lowered the productivity, increased the probability of severe or chaotic events, and decreased the similarity to the temporal, spatial, and habitat diversity of the native system.

Historically, the Leaf Area Index (LAI) for the woodland PVG averaged approximately 2.7, (range = 1 to 24; sd = 2.5). In the current period, the LAI had a mean of 4.4, (range = 0.2 to 32; sd = 3.6). The higher LAI related to the total increase in woody foliage. The large range of values and relatively higher standard deviation generally indicates a less predictable condition.

Dry Forest PVG

During the current period, 69 percent of dry forest PVG occurred above 1,200 meters elevation; 31 percent occurred below 1,200 meters (table 3.18). The dry forest PVG composed 18 percent of the Basin. BLM/FS lands contained 56 percent of the dry forest PVG (maps 3.11 and 3.12). We detected about a 1 percent loss of this type between the historical and current periods, which was mostly attributable to agricultural and urban development on Other land ownerships. Given the current trend of rural development in the dry forest PVG and our low resolution of information pertaining to development, the decrease of this type has probably been more substantial than was indicated and will likely continue into the future.

In general, the dry forest PVG is limited by low moisture availability, but could also be limited by nutrient deficiencies where the surface soil has been eroded or displaced, or tree stocking levels have become dense. In the dry forest PVG, growth rates are generally slow for small regenerating trees and mature trees in dense communities, but are faster for open-grown trees with good root systems. The duration of the herb, shrub, and early-seral forest structures stages are relatively long, often of almost equal length as the mid-seral stage. Shrub and grass structures are fairly productive in open communities, but relatively unproductive in closed communities.

In native disturbance regimes, small tree mortality due to fire, insects, disease, and competition from other trees was common prior to fire suppression. In general, the native system maintained a fairly constant unchanging pattern of open communities with approximately 20 to 50 percent composition in late-seral single-layer structures; 10 to 15 percent in late-seral multi-layer structures; 25 to 30 percent in mid-seral structures; 10 to 20 percent in open and mixed (tree, shrub, and grass) early-seral structures; and 0 to 15 percent in herb and/or shrub structures (table 3.32). The late-seral single-layer structure was maintained by understory fires, which typically occurred in areas of more gentle or

rocky terrain. Patches of early- to mid-seral stages generally occurred in steep areas where fires would carry into the crown. These crown fires were promoted by topographic wind funneling, a high probability of wind events due to geographic location, and poor site productivity, such that most trees would not grow tall enough between fire intervals to survive typical flame lengths. Fire intervals in the dry forest PVG, prior to suppression, generally ranged from 20 to 70 years. In general, the native fire regime of the dry forest PVG consisted of approximately 80 percent nonlethal underburning fires, 5 percent mixed fires, and 15 percent crown fires, usually topographically arranged as described above. The fire season was relatively long in this type, starting in June and extending into September.

Late-seral tree species in the dry forest PVG were shade-tolerant, relatively slow growing, and were generally highly susceptible to mortality from fire, insect attacks, and root disease. In contrast, early-seral, shade-intolerant, relatively fast-growing species were typically much less susceptible to mortality from fire, insect attacks, and root disease. In the native system, the early-seral forest was dominated by shade-intolerant species composing 10 to 20 percent of the PVG, as compared with approximately 1 to 3 percent dominance by shade-tolerant species (table 3.33). In the mid-seral forests, shade-intolerant and shade-tolerant species dominated about 15 to 20 percent, and 10 percent of the PVG, respectively. The late-seral single-layer stage was dominated by shade-intolerant species composing 20 to 45 percent of the PVG, as compared to 1 to 2 percent for shade-tolerant species.

[3]+ = < 0.5%

Late-seral multi-layer stages were dominated by shade-intolerant species ranging from 5 to 10 percent of the PVG, as compared to 3 to 5 percent for shade-tolerant species.

Since the implementation of fire suppression and traditional silvicultural practices, the dry forest PVG generally shifted to a predominance of mid-seral structures, which occupied approximately 55 percent of the landscape (table 3.32). Historically common, the large, scattered, residual tree component was typically missing from areas that had been harvested. In the current period, much of the dry forest PVG was dominated by a higher density of smaller-diameter trees due to the lack of thinning fires that accelerated the growth rates of fire survivors. The current period areal extent of the late-seral multi-layer structure was at the upper end of its historical range (approximately 16% composition). During the current period, early-seral physiognomic types generally occurred within their historical range, but areas that had been harvested were missing the scattered, large-diameter trees and snags. Exotic plants invaded the dry forest PVG, and were a common component of early-seral herbland and shrubland, and the late-seral single-layer physiognomic types in the current period. The similarity of physiognomic type composition between historical and current periods was 66 and 74 percent for the Basin as a whole, and for BLM/FS lands, respectively (table 3.31).

The ratio of shade-tolerant to shade-intolerant tree species' dominance changed in the dry forest PVG (table 3.33). The amount of early-seral shade-tolerant and shade-intolerant forests were both at the upper end of their historical range (3 and 15%, respectively). The current period abundance of mid-seral structures consisting of shade-tolerant species occurred at nearly twice their historical amounts. In the current period, areal extent of the mid-seral shade-intolerant forest was approximately 50 percent greater than the historical level; it composed about 35 percent of the dry forest PVG. The late-seral multi-layer structure had approximately twice as much dominance by shade-tolerant species; the current areal extent of shade-intolerant species was less than 25 percent of its historical range. The composition of late-seral single-layer shade-tolerant forest had not changed substantially, but the late-seral single-layer shade-intolerant forest had declined by 25 percent from historical amounts. Consequently, current period landscapes had a mixed composition rather than being dominated by shade-intolerant species. This was particularly true in areas that had been actively harvested and in areas where fire suppression has been effective.

The dry forest PVG occurs in a stressful climatic environment that is often subject to drought. In the unaltered biophysical template, approximately 15 percent of the PVG was dominated by shade-tolerant species. During the current period, the composition of shade-tolerant species in the dry forest PVG was nearly twice that amount. Relative to the historical period, communities were generally more dense and had larger amounts of carbon and nutrients tied up in woody material. As a result, much of the land base in the current period dry forest PVG where management has been extensive (for example, road building, harvesting, planting, thinning, and so on), was highly susceptible to tree mortality from fires, insects, disease, and water stress.

In general, the dry forests that had the highest departure from the unaltered biophysical template, were those that had been harvested, favoring the removal of high value, large, shade-intolerant tree species [for example, ponderosa pine (*Pinus ponderosa*)] and leaving shade-tolerant, fire- and insect/disease-susceptible species [for example, Douglas-fir (*Pseudotsuga menziesii*)].

Fire suppression was generally more effective in the roaded areas. The combination of past harvest practices and more effective fire suppression moved the roaded landscapes much further from their unaltered biophysical templates, as measured by dominant species, structures, and patterns,

relative to unroaded areas. Approximately 1 percent of the dry forest PVG was converted to agriculture and urban types, typically on Other lands adjacent to public lands. The dense mid-seral structures of the dry forest PVG have high risks for crown fire and intense fire events. The current period fire interval doubled or tripled to approximately 40 to 80 years, as a result of the more recent fire suppression programs and improved access. Increasing fire intervals without a corresponding reduction of fuels have produced higher fuel loads and higher fire intensities in recent years. Current period fire regimes within the dry forest PVG comprised 20 percent lethal crown fires, 35 percent mixed fires, and 45 percent non-lethal underburn fires. The similarity of fire regimes between historical and current periods was 17 and 20 percent for the Basin as a whole and BLM/FS lands, respectively (table 3.31).

The development of houses and other cultural facilities in or adjacent to dry forest types has become problematic, increasing fire potential, and decreasing efficient suppression. Consequently, it is rapidly becoming more difficult to protect human lives and property.

The LAI did not change substantially. Historically, it averaged approximately 8.4 (range = 1.8 to 21.5; sd = 4.0). During the current period, the LAI had a mean of 9.6 (range = 0.2 to 58.6; sd = 7.3). The upward trend of the LAI was consistent with the observed increase of overall biomass. The standard deviation and range were considerably higher in the current period compared to the historical period, indicating a less predictable system.

The dry forest PVG was rated high in terms of overall departure of succession and disturbance ratings. The similarity of succession/disturbance regimes between historical and current periods was 11 and 20 percent for the Basin as a whole and BLM/FS lands, respectively (table 3.31). The relatively high departure was attributed to road and harvest systems, changes in landscape vegetation composition and structure, and changes in the fire regime. To a lesser degree, the departure was also related to the invasion of exotic vegetation. Consequently, the current period dry forest PVG had lower productivity, higher probability of severe or chaotic events, and lower similarity to the temporal, spatial, and habitat diversity of the native system.

Moist Forest PVG

Approximately 40 percent of the moist forest PVG occurs at elevations below 1,200 meters; 60 percent occurs at elevations above 1,200 meters (table 3.18). The moist forest PVG composes 18 percent of the Basin, of which nearly 64 percent occurs on BLM/FS lands (maps 3.11 and 3.12). Agricultural or urban development was responsible for only a very minor loss (< 0.5%) of this type from historical to current times.

The moist forest PVG typically has relatively high soil moisture availability in the spring and early summer, but experiences drought stress in the late summer and early fall. Nutrient availabilities can also be limiting in this PVG. Nutrients are commonly depleted through timber harvest practices or through multiple burns, which displace or erode surface soil, or remove too much of the large woody material, litter/duff, or small branch needle/leaf foliage that carries the bulk of the nutrient capital. In general, rates of tree growth are fairly rapid and the early-seral structural stage is typically short-lived in comparison to the mid-seral stage.

The native system for the moist forest PVG was fairly dynamic. The early-seral forest structure composed 20 to 30 percent of the PVG, fluctuating to either end of the range in as little as 50 years. The mid-seral structure composed 40 to 50 percent of the moist forest PVG, typically being cycled back to the early-seral stage by lethal crown or mixed-fire events. However, in many cases, underburns or mixed-fire regimes maintained the mid-seral stage or moved it into the late-seral single-layer stage. The mid-seral structure composed 5 to 10 percent of the PVG. The late-seral multi-layer structure typically developed in cool, moist bottoms and basins where fires generally

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

burned in a creeping, low-intensity behavior, maintaining the stage with a gap mosaic pattern. Late-seral structures historically composed 20 to 30 percent of the PVG.

Native fire regimes within the moist forest PVG were variable. Non-lethal underburns occurred at relatively frequent intervals (15-25 years) on benches and ridges that composed about 25 percent of the PVG. Lethal crown fires varied from 20 to 150 years, and generally occurred in the upland slope environments across 25 percent of the moist forest PVG. The mixed-fire regime occurred across 40 to 45 percent of this PVG with highly variable intervals most commonly ranging from 20 to 150 years, but with some at intervals of up to 300 years. The fire season was relatively short, generally starting in July and extending into September. Typically, most fires were very small, but occasionally, some fires grew very large.

In the native system, the early-seral forests were dominated by shade-intolerant species that composed 15 to 25 percent of the moist forest PVG, as compared to approximately 5 percent composition of shade-tolerant species (table 3.34). In mid-seral physiognomic types, shade-intolerant species dominated about 28 to 35 percent of the PVG, as compared to 6 to 15 percent for shade-tolerant species. The late-seral single-layer physiognomic type was dominated by shade-intolerant species that composed 5 to 10 percent of the PVG, as compared to 1 percent for shade-tolerant species. The late-seral multi-layer shade-intolerant physiognomic type averaged about 15 percent composition of the PVG, whereas shade-tolerant species dominated 5 to 15 percent of the PVG. In areas having relatively infrequent fire intervals, there were long periods where shifts from shade-intolerant to shade-tolerant species occurred over 50 to 150 years, due to natural succession processes. The variability in the shade-tolerant species dominance of the late-seral multi-layer system was generally due to this cyclic shift.

The moist forest PVG has changed since the implementation of fire suppression and traditional silvicultural activities (table 3.35). In general, the forests that had the greatest departures from the unaltered biophysical template were those that have been roaded and harvested with clearcuts or partial cuts, favoring the removal of large, shade-intolerant tree species [for example, western larch (*Larix occidentalis*), western white pine, and ponderosa pine] and leaving shade-tolerant fire- and insect/disease-susceptible species [for example, grand fir (*Abies grandis*), western redcedar (*Thuja plicata*), western hemlock (*Tsuga heterophylla*), and Douglas-fir]. Fire suppression has also been more effective in roaded areas, and consequently, changed the composition and structure within those areas. These effects have been compounded by the extensive loss and poor regeneration of western white pine as a result of white pine blister rust infestations.

The similarity of the composition of physiognomic types between historical and current periods was 70 and 78 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). In the current period, the areal extent of the early-seral physiognomic type (20%) was at the low end of its historical range. Most of the disturbances that created early-seral physiognomic types were even-age harvests (for example, clearcuts and seed tree cuts). These activities did not retain the snag structure or create an environment that could maintain the historical community composition and structure. Consequently, most current period early-seral structures within this PVG were very different in composition and structure relative to the native biophysical template. The areal extent of the mid-seral forest physiognomic types (approximately 70%) were more abundant in the current period than those which typically occurred in native systems. Most of the current period mid-seral stage had much higher tree densities and higher fuel loadings than were typically present in the native system. In addition, within roaded areas, many of the large, scattered, residual trees have been harvested, which also dramatically changed the community structure.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

The ratio of shade-tolerant to shade-intolerant tree species' dominance changed in the moist forest PVG from the historical to the current period. The current period proportion of the early-seral shade-tolerant type was about the same as the native system, but the abundance of the early-seral shade-intolerant physiognomic type decreased substantially. The current period areal extent of the mid-seral shade-tolerant forest was almost three times its historical range, whereas the amount of current period shade-intolerant forest was at the upper end of its historical range. The shade-intolerant species which historically dominated the late-seral single-layer stage had essentially been lost, while shade-tolerant species dominating this stage doubled.

In the current period, multi-layer late-seral physiognomic type, shade-intolerant species constituted only 20 percent of the historical abundance, whereas the dominance of shade-tolerant species had not changed substantially. Most current period landscapes within the moist forest PVG were dominated completely by shade-intolerant species, or a mixture of shade-tolerant and shade-intolerant species. This change was particularly evident in areas that were actively harvested and where fire suppression has been highly successful.

The moist forest PVG has a productive environment that can rapidly produce biomass and accumulate fuel, and where insects and pathogens are

potentially very active. The exotic blister rust, as well as past harvest activity, has caused a decline in western white pine. As a result, much of the moist forest PVG comprises a mixture of compositions and structures that are highly susceptible to mortality from fires, insects, disease, and stress.

The similarity of fire regime composition between the historical and current periods was 47 and 51 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). The current period fire regime has become simplified relative to the historical regime. As a result of higher fuel loads, increased stocking levels of trees, and high late summer moisture stress levels, most of the moist forest PVG shifted to lethal crown fire or mixed-fire regimes. About 10 percent of the PVG, typically associated with the single-layer late-seral or open mid-seral physiognomic types, retained a non-lethal underburn potential. Approximately 60 to 70 percent of the PVG had a high potential for crown fire, and 20 to 30 percent of the type had a mixed-fire regime. With recent suppression efforts, the general fire interval had almost tripled in length to approximately 75 to 150 years. Increasing fire intervals without a corresponding reduction in fuels have resulted in higher-intensity fires.

The LAI for the moist forest PVG did not change substantially between historical and current periods. Historically, the LAI averaged approximately 13.2 (range = 5.2 to 36.8; sd = 6.0). In the current period, the LAI had a mean of 14.6 (range = 0.2 to 57.9; sd = 8.0). This trend was consistent with the observed increase in biomass of the moist forest PVG. The higher LAI standard deviation and range indicated a less predictable system.

The departures of succession and disturbance processes were high within the moist forest PVG. The similarity of succession/disturbance regime composition between historical and current periods was 23 and 28 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). High departures were a consequence of road and harvest systems, changes in landscape vegetation composition and structure, the invasion of blister rust on western white pine, and changes in the fire regime. These changes decreased productivity, increased the probability of severe or chaotic events, and decreased the similarity to the temporal, spatial, and habitat diversity of the native system.

Cold Forest PVG

Most (99%) of the cold forest PVG occurs above 1,200 meters elevation (table 3.18). Although the cold forest PVG dominated higher elevations, it only accounts for 10 percent of the Basin; BLM/FS lands contain most (87%) of the cold forests (maps 3.11 and 3.12). There was essentially no loss of the cold forest PVG as a result of agricultural or urban development from the historical to the current period.

The cold forest PVG is generally limited by a short growing season, and on some sites, also by low available moisture. Rates of tree growth are relatively slow. Shrub and grass productivity are variable depending on soil types. The duration of the early-seral structural stage is relatively long, often almost the same duration as the mid-seral structural stage. Nutrients are often limiting, and loss of ash, litter, surface soil, or tree foliage from the site can greatly reduce productivity. Maintenance of dead and down wood on these sites is particularly important for nutrient cycling.

Native cold forest systems generally maintained a fairly high composition of the late-seral multi-layer structure, typically in cold, wet bottoms or basins where fires rarely burned, or burned in a patchy, low-intensity gap mosaic pattern. The late-seral single-layer structure was typically maintained by underburning fires on benches and ridges that were dominated by whitebark pine and lodgepole pine. Areas on moist to wet, steep slopes typically burned with lethal crown fires at intervals that generally only allowed the development of early- to mid-seral structures. These fires varied in intensity leaving scattered, large, residual trees; small patches of green trees in seep areas; and dead-standing snags. On occasion, fires reburned within a short period of time, producing open grass and shrub

structures that could persist for relatively long periods before regenerating into forests. Tree mortality from stress, insects, and disease generally thinned the communities and accelerated the growth of surviving trees. Minor amounts of early- and mid-seral riparian woodlands developed along narrow stream courses. The composition of the native cold forest PVG typically comprised the late-seral single-layer (6-8%), late-seral multi-layer (15-24%), early-seral (23-25%), and mid-seral (44-53%) physiognomic types (table 3.36).

Historically, fire intervals in the cold forest PVG were highly variable and correlated with landforms. The non-lethal underburning regime that maintained the late-seral single-layer and some mid-seral physiognomic types, generally comprised approximately 10 percent of these landscapes, and typically occurred on ridges and flat benches. The fire-return interval on these landforms varied from 30 to 100 years. The lethal crown-fire regime generally occurred across 25 to 30 percent of the cold forest PVG, and had a fire-return interval which varied from 25 to 300 years. Shorter intervals generally occurred on steeper slopes recycling mid-seral to early-seral physiognomic types. Longer intervals occurred in wet bottoms and basins, which typically supported the late-seral multi-layer physiognomic type. The mixed-fire regime was most common and occurred throughout 60 percent of the PVG; mixed-fire return intervals varied from 25 to 300 years. The mixed-fire regime was often intermingled with the other regimes, either during one fire event or through a series of fire events. The cold forest PVG had a relatively short fire season, generally only lasting for the month of August. Most fires were very small, but a few occasionally grew very large.

The similarity of physiognomic type composition between the historical and current periods was 81 percent for the Basin as a whole and for BLM/FS lands (table 3.31). In the historical system, the early-seral physiognomic type was dominated by shade-intolerant species that composed 16 to 21 percent of the PVG, whereas shade-tolerant species in this type composed approximately 5 percent of the PVG (table 3.37). Shade-intolerant species in the mid-seral physiognomic type dominated about 30 percent of the PVG, as compared to a 15 to 21 percent composition of shade-tolerant species. The late-seral single-layer physiognomic type was dominated by shade-intolerant species (5-6%) relative to shade-tolerant species (≤ 2%).

The late-seral multi-layer physiognomic type had a different composition. Shade-tolerant species composed 8 to 15 percent of the late-seral multi-layer physiognomic type, whereas shade-intolerant species composed 7 to 9 percent. The above-mentioned relationship was consistent with the long fire intervals and landforms where the late-seral multi-layer physiognomic type occurred. The lack of frequent disturbance events allowed succession to proceed and shade-tolerant species to become established.

The cold forest PVG changed substantially as a result of fire suppression and traditional silvicultural activities (table 3.36). In general, the cold forests that had the highest departure from the unaltered biophysical template were those that had been roaded and harvested with clearcuts, other traditional even-age harvest prescriptions, or partial cuts. Much of the late-seral multi-layer forest type had been harvested between the historical and current periods, reducing its areal extent to approximately 10 percent of the PVG. Although the areal extent of the late-seral single-layer physiognomic type did not change substantially, we believe that the composition of many of these types was altered by the loss of whitebark pine due to blister rust infestation. The areal extent of the early-seral physiognomic type increased to approximately 30 percent of the cold forest PVG, generally as a result of timber harvest. Essentially, much of the early-seral stage was created by harvesting the high volume, late-seral multi-layer physiognomic type. In addition, timber harvest removed most of the snag component that occurred historically. The current period abundance of the mid-seral type (45%) was within its historical range. However, many areas that had been harvested with

partial or selective cuts did not retain the large, scattered, residual trees that were common in the historical mid-seral physiognomic type.

The ratio of shade-tolerant to shade-intolerant tree species changed greatly within the cold forest PVG between the historical and current periods (table 3.37). Since the historical period, the amount of early-seral shade-tolerant forests has nearly doubled. Similarly, the areal extent of mid-seral shade-tolerant forests is also substantially higher than their historical range, whereas the amount of shade-intolerant mid-seral forests has declined substantially. The ratio of shade-tolerant to shade-intolerant species dominating the late-seral single-layer and multi-layer physiognomic types has not changed substantially, given the overall areal decline of both types.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

The cold forest PVG evolved with shade-intolerant species dominating the early-seral and mid-seral physiognomic types. In the current period, early- and mid-seral structures were dominated by either a mixture of shade-tolerant and shade-intolerant species, or shade-tolerant species alone. This was particularly true in areas that had been logged, and where fire suppression had been effective. Much of the current period cold forest PVG appeared highly susceptible to tree mortality from fires, insects, disease, and stress.

The similarity of fire regime composition between historical and current periods was nearly 65 percent, regardless of land ownership strata (table 3.31). In most areas of the cold forest PVG, tree densities and fuel loads increased substantially as a result of fire suppression. Historically, the mixed-fire regime in the cold forest PVG reduced fuels and thinned tree densities, thereby accelerating the growth rate of survivors. Under existing fire suppression programs, the fire interval had increased from 75 to 300 years. Although the change in fire interval was substantial, as in the dry forest and moist forest PVGs, the changes in landscape structure and composition in the cold forest PVG typically resulted in higher fuel loads and fire intensities. When fires did occur, in what was historically a more frequent fire interval, they tended to be large, lethal, crown-fire events of high intensity (particularly on upland slope environments).

The LAI within the cold forest PVG did not change substantially between the historical and current periods. Historically, the LAI averaged approximately 9.0 (range = 3.1 to 24.3; sd = 3.2). In the current period, the LAI had a mean of 8.3 (range = 0.2 to 43.6; sd = 8.3). The observed trend was consistent with the general indication that biomass decreased as a result of past timber harvest patterns and declines in whitebark pine. The increased standard deviation and range suggested a less predictable system.

The similarity of succession/disturbance regime composition between historical and current periods was approximately 26 percent, regardless of land ownership strata (table 3.31). Succession and disturbance departure ratings in the cold forest PVG were moderate. Moderate departures were a consequence of changes in broad-scale vegetation composition and structure, which resulted from timber harvest, blister rust impacts on whitebark pine, and changes in the fire regime. Relative to the moist forest PVG, the cold forest PVG had experienced less of a departure, primarily because the above-listed effects occurred more slowly in these cold environments. However, long-term projected outcomes would be similar — namely, lower productivity, higher probability of severe or chaotic events, and lower similarity to the temporal, spatial, and habitat diversity of the native system.

Dry Grass PVG

During the current period, 42 percent of the dry grass PVG occurred below 1,200 meters elevation; 58 percent occurred above 1,200 meters (table 3.18). The current period dry grass PVG composed 4 percent of the Basin. Historically, however, this PVG was more extensive, occurring across 9 percent of the Basin. Agricultural and urban development was responsible for the 56 percent areal decline of the dry grass PVG. The distribution of the dry grass PVG has also changed greatly (maps 3.11 and 3.12). Historically, 69 percent of this type occurred below 1,200 meters elevation and 31 percent occurred above 1,200 meters. Current period BLM/FS lands contained 44 percent of the remaining dry grass PVG (table 3.18). Much of the dry grasslands were converted to dryland agricultural croplands or pastures. In general, on Other lands, we believe that most of the dry grasslands having agricultural potential have already been converted. Consequently, we expect little loss of this dry grass PVG to future agricultural development. However, given the current trend of increased rural development on private lands within this PVG, it was assumed that the overall decrease in the dry grass PVG would continue into the future, but at a slower rate.

The dry grass PVG is limited by available moisture, either due to low rainfall or to shallow, rocky, or clay soils. Native communities are very diverse with various grasses, forbs, and sedges, and have fair production in years of good fall or winter moisture. Historically, the dry grass PVG existed primarily in north-central Oregon, southeast Washington, and north-central Idaho (map 3.11). Approximately 29 to 34 centimeters of precipitation was received during the fall-winter or winter-spring periods in these areas (table 3.38; climate divisions: Oregon North Central, Washington Palouse-Blue Mountains, and Idaho North Central Prairies). Drought years in which less than 75 percent of the fall-winter or winter-spring precipitation was received occurred between 7 and 17 percent of the time. Conversely, relatively wet periods, characterized by two or more successive years of greater than 110 percent of the fall-winter or winter-spring precipitation, have been documented only 3 to 6 times in the 100-year period (1895-1994). Thus, drought was a frequent occurrence, whereas successive wet years, believed to be critical for perennial plant recruitment, were somewhat less frequent.

Most of the dominant grass and forb species within the dry grass PVG have adapted to a cool-season moisture regime where moisture arrived primarily in the fall, winter, and spring, followed by a dry summer. These species were highly dependent upon soil moisture storage from cool-season precipitation, and conducted most of their growth and reproductive activities during the spring and early summer. In general, shrubs that are able put down deeper root systems for stored winter moisture attainment are more competitive on dry grasslands experiencing the absence of fire. Cool-season species typically become dormant in the summer and early fall, however, adequate fall moisture can stimulate an additional growing period.

In the eastern portion of the Basin, more plant species have adapted to the warm-season moisture that occurs primarily in the spring and summer. Warm-season species have adapted to take advantage of available moisture throughout the growing season. In general, grasses are more competitive than shrubs in environments where moisture is available throughout the growing season. The dry grass type is much more common in areas that have high numbers of cloudy days during the winter and spring. Sagebrush species can photosynthesize during the winter period, but in areas that receive relatively little winter sunlight this adaptation is not conducive to sagebrush establishment or to its ability to compete successfully with herbaceous species.

In the absence of fire, shrubs and trees eventually invade much of the dry grass PVG area that lies adjacent to the dry shrub, woodland, or dry forest PVGs. Soil characteristics of the dry grass PVG generally indicate that they developed in conjunction with grassland potential vegetation. When these sites are invaded by shrubs and/or trees, nutrient regimes often change.

Woody species tie up nitrogen and other trace nutrients causing a decline of site productivity. Subsequently, foliage cover, basal cover, and litter from the grasses and forbs decline, causing exposure of the surface soil to erosion. Erosion potentials in these areas can be aggravated by excessive grazing pressure from livestock and wild ungulates. Once the surface soil becomes eroded and the subsoil is exposed, the environment becomes more conducive to the woody species that better compete for subsoil moisture.

In general, the historical system of the dry grass PVG was dominated by an upland herbland physiognomic type which was, in turn, dominated by grasses and forbs (table 3.39). The upland herbland physiognomic type typically burned with non-lethal fires; non-lethal fires stimulated existing forbs the year following the fire event, and eventually caused the vegetation to revert to dominance by existing grasses. Small vegetation patches with decadent grasses and high accumulations of litter were killed, creating small openings for early-seral forbs. Regeneration from shrubs or tree seeds were generally killed by drought or fire. Historically, the early-, mid-, and late-seral woodland

[3]+ = < 0.5%.

physiognomic types constituted about 5 to 10 percent of the dry grass PVG (table 3.39), typically along the ecotones with the dry shrub, woodland, and dry forest PVGs. When these types burned, they usually exhibited mixed-fire behaviors.

The native grazing regime appears to have varied between relatively high- intensity short-duration grazing, to extensive low-intensity grazing, to seasonally-moderate levels of grazing by ungulates. Grazing patterns were strongly influenced by seasonal weather, greenness of foliage during the growing season, or the palatability of foliage in the winter season. The majority of fires in the dry grass PVG were non-lethal and occurred at intervals ranging from 5 to 75 years throughout 90 percent of the PVG. Mixed-fire events typically occurred in dry grass types that had developed into shrub or woodland physiognomic types, but also in herb-dominated areas with high accumulations of litter and decadent plants. Mixed-fire regimes occurred in approximately 10 percent of the dry grass PVG. The fire season was relatively long in dry grasslands; it generally started in April or May and lasted into October.

The dry grass PVG changed due to fire suppression, livestock grazing, invasion of exotics, and conversion to agricultural and urban land uses (table 3.39). The similarity of physiognomic type composition between historical and current periods was 61 and 69 percent for the Basin as a whole and BLM/FS lands, respectively (table 3.31).

Exotic herblands, particularly those containing annual grasses and knapweeds (*Centaurea* spp.), dominated at least 5 percent of dry grasslands during the current period. Exotic species were common components of most communities of the dry grass PVG. With the exception of the agricultural PVG, the dry grass PVG was the most susceptible to exotic plant invasion of all the PVGs in the Basin (see fig. 3.14).

The early-seral and mid-seral woodland physiognomic types did not increase substantially, but the current period late-seral woodland physiognomic type was at the upper end of its historical range. The composition and structure within upland herbland physiognomic types changed as a result of heavy early-season or season-long livestock grazing, and seeding to perennial exotic grasses such as crested wheatgrass (*Agropyron cristatum*). Large dominant bunchgrasses that occurred historically were generally replaced by smaller bunchgrasses, forbs, annual exotic grasses, exotic forbs, and seeded exotic grasses. Seeded exotic grass ranges were similar in structure to native bunchgrass ranges, but plant diversity was often lower in the seeded exotic grass ranges.

In general, the highest departures from the unaltered biophysical template within the dry grass PVG occurred in areas that had been subjected to high levels of continuous season-long or early-season grazing, and were extensively roaded (improving the efficiency of fire suppression, while also providing a conduit for the dispersal of exotics). The similarity of fire regime composition between historical and current periods was 44 and 65 percent for the Basin as a whole and BLM/FS lands, respectively (table 3.31). Current period fire regimes were approximately 50 percent non-lethal and 50 percent mixed. Due to fire suppression, the fire intervals have increased from approximately 25 to 75 years. Fuels generally did not increase on the upland herbland physiognomic types since they were typically grazed. However, vigor of the dominant grasses and forbs decreased in these types due to the continued absence of fire.

Fuels accumulate when shrubland and woodland encroachment occurs. During drought years, very intense fire events can occur in areas of woody encroachment, often causing relatively severe effects to the soil surface and mortality to the understory grasses and forbs.

The LAI within the dry grass PVG did not change substantially between the historical and current periods. Historically, the LAI averaged 2.4 (range = 1.9 to 7.8; sd = 0.8). The mean LAI of the current period was also 2.4 (range = 0.2 to 51.9; sd = 1.9). The current system LAI standard deviation and range suggested that the current system was less predictable than the historical system.

The departure of succession and disturbance processes were rated high for the dry grass PVG. The similarity of succession/disturbance regimes between historical and current periods was 6 and 21 percent for the Basin as a whole and BLM/FS lands, respectively (table 3.31). This was a consequence of agricultural and urban development, and altered grazing and fire regimes that differed from the disturbance regimes of the unaltered biophysical template. There was a subsequent decrease of productivity, increase in probability of severe or chaotic events, and decreased similarity to the temporal, spatial, and habitat diversity of the native system.

Dry Shrub PVG

The majority (71%) of the current period dry shrub PVG occurred above 1,200 meters elevation; 29 percent occurred below 1,200 meters (table 3.18). Since the historical period, the areal extent of the dry shrub PVG decreased by approximately 30 percent as a result of agricultural and urban

development. Historically, a greater proportion of the dry shrub PVG (40%) occurred below 1,200 meters elevation. In the current period, BLM/FS lands contained 55 percent of the remaining dry shrublands. A large proportion of this type was converted to dryland or irrigated agricultural croplands, haylands, or pastures (maps 3.11 and 3.12). Given the current trend of increased rural development on the private lands within the dry shrub PVG, we conclude that the declining trend would likely continue into the future, but at a slower rate.

In general, the dry shrub PVG is limited by moisture availability, either due to low rainfall or to shallow, rocky, or clay soils. Native communities are very diverse and have many species of shrubs, grasses, forbs, and sedges. Production is fair in years of good fall, winter, or spring moisture. The dry shrub PVG historically existed primarily in eastern Washington, southeastern Oregon, and southern Idaho (map 3.11). In these areas, approximately 15 to 21 centimeters of precipitation was received during the fall-winter or winter-spring periods (table 3.38; climate divisions: Washington Central Basin, Oregon South Central, Oregon Southeast, Idaho Southwest Valleys, Idaho Central Plains, and Idaho Upper Snake River Plains). Drought years, in which less than 75 percent of the fall-winter or winter-spring precipitation was received, occurred approximately 15 to 18 percent of the time in these areas. Conversely, relatively wet periods were documented only 6 to 8 times in the 100-year period (1895-1994). Thus, drought frequency, and above-normal precipitation frequency, are greater for the dry shrub PVG compared with the dry grass PVG. The dry shrub PVG is more arid than the dry grass PVG, but along with the greater aridity is a greater variability of precipitation received.

Most of the dominant shrub, grass, and forb species found within the dry shrub PVG have adapted to a cool-season moisture regime, when moisture arrives primarily in the fall, winter, and spring and is followed by a dry summer. The herb and shrub species are highly dependent upon soil moisture stored in the soils from fall, winter, and spring precipitation. Most of their growth and reproduction occurs during the spring and early summer. The cool-season species typically become dormant in the summer and early fall, but can become active again in the fall with adequate moisture. There are a greater number of plant species in the eastern portion of the Basin that have adapted to warm-season moisture — moisture that comes proportionately more in the spring and summer. These species have adapted to take advantage of available moisture throughout the growing season. In general, grasses become more competitive toward the eastern edge of the Basin.

Historically, the dry shrub PVG moved through fairly short cycles of dominance by upland herbland or upland shrubland physiognomic types due to the relatively short-fire intervals. In the absence of fire, trees can invade dry shrub PVGs that lie adjacent to woodland or dry forest PVGs. Soil characteristics of the dry shrub PVG generally indicate that they developed with mixed shrub and grassland potential vegetation. Shallow soils are typically dominated by low shrubs, whereas deep soils are potentially dominated by mid to tall shrubs. Tree establishment in the dry shrubland PVG disrupts the established nutrient regime. Tree species tie up nitrogen and other trace nutrients, thereby decreasing overall site productivity. Subsequently, foliage cover, basal cover, and litter from the shrubs, grasses, and forbs decline, thereby exposing the surface soil and increasing erosion potential. Erosion is potentially aggravated by excessive grazing pressure from livestock and wild ungulates. Once the surface soil is eroded and the subsoil exposed, the environment is more conducive to tree species that are more competitive for subsoil moisture.

In general, the native system was dominated by a mosaic of upland shrubland and upland herbland physiognomic types, depending on the interval between fire disturbances. The dry shrub PVG typically burned with a mixture of non-lethal fires

in areas dominated by upland herbs, and lethal fires in areas dominated by shrubs. Most fires in the dry shrub PVG that were lethal occurred at intervals from 15 to 100 years, and dominated about 90 percent of the PVG. Non-lethal fires occurred across 10 percent of the PVG at intervals of 5 to 10 years, and generally reburned upland herbland physiognomic types. The fire season was relatively long in the dry shrub PVG, generally starting in April or May and extending into October.

Fires in the dry shrub PVG typically kill the shrubs and stimulated established forb species during the year following a disturbance. Succession on these burned sites results in the dominance of established grass species. In small patches with high amounts of decadent or dead shrubs, decadent grasses, and high accumulations of litter, fire often kills the existing perennial grasses and forbs, making small openings for early-seral forbs. Regeneration of shrubs and trees are generally killed by drought or fire.

Historically, the early-, mid-, and late-seral woodland physiognomic types were never able to persist, due to the relatively high intensity and continuity of fire within the shrubland types. The upland herbland physiognomic type constituted 10 to 60 percent of the native dry shrub PVG, depending on the temporal period of the fire cycle. Similarly, the upland shrubland physiognomic type occurred across 40 to 90 percent of the PVG. Areas with mosaic patterns of upland herbs and upland shrubs typically occurred in rough terrain or rocky areas. Areas with continuous patterns of upland herbs or upland shrubs were usually located on more uniform terrains. The native grazing regime was similar to that of the dry grass PVG.

The similarity of physiognomic type composition between historical and current periods was 79 and 93 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). The dry shrub PVG changed from the historic to the current period in much the same manner as the dry grass PVG (table 3.40). The only exception in similarity was that woodland physiognomic types did not greatly increase in the dry shrub PVG. As with the dry grass PVG, the highest departures from the biophysical template within the dry shrub PVG occurred in areas subjected to high levels of continuous season-long or early-season grazing with extensive roading.

The similarity of fire regime composition within the dry shrub PVG between historical and current periods was 29 and 35 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). The current period fire regime within dry shrublands was dominated by lethal fires, which typically occurred at 3 to 15 year intervals. Areas experiencing more frequent fire intervals often had a high component of annual exotic grasses that dried early in the season and became flash fuels for fast-moving summer fires. The additional abundance of fine, flash-type fuels, combined with sagebrush fuels, creates intense fires. Most perennial vegetation in the dry shrub PVG is not adapted to these more frequent, high-intensity fires; the eventual result is mortality of perennial species and prevention of their recruitment. We expect an expansion of this shift in fire regimes over the next 50 years, which will convert even more of the dry shrub PVG to annual exotic grasses.

When woodland encroachment occurs, fuels accumulate and communities exhibit high stress and low foliage moisture. During drought years, very intense fire events can occur in areas of woody encroachment, often causing relatively severe effects to the soil surface and mortality to the understory grasses and forbs.

We did not detect a change in the LAI for the dry shrub PVG between the historical and current periods. Historically, the LAI averaged approximately 1.6 (range = 1.1 to 15.1; sd = 0.3). During the current period, the LAI also averaged 1.6 (range = 0.2 to 51.9; sd = 0.9); however, the increased standard deviation and range of the current period suggested that the system was less predictable than it was historically.

[3]+ = < 0.5%.

The departures and subsequent effects of succession and disturbance processes of the dry shrub PVG were similar to those identified for the dry grass PVG. The similarity of succession/disturbance regimes between historical and current periods was 10 and 19 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31).

Cool Shrub PVG

Most (75%) of the current period cool shrub PVG occurred above 1,200 meters elevation, whereas historically, 69 percent of the PVG occurred above 1,200 meters elevation (table 3.18). Since the historical period, the areal extent of the cool shrub PVG decreased by approximately 11 percent as a result of agricultural and urban development (maps 3.11 and 3.12). The BLM/FS lands contained most (66%) of the cool shrub PVG. We expected that there would be little loss of cool shrublands to agricultural or urban development in the future. The current trend of rural development on private lands appeared to be low within the cool shrub PVG. Consequently, we conclude that the abundance of the cool shrub PVG will remain relatively constant in the future.

Productivity within the cool shrub PVG is limited by short growing seasons and by low available soil moisture, due to either low rainfall or shallow, rocky, or clay soils. Native communities are very diverse, containing many species of shrubs, grasses, forbs, and sedges. Production is good in years with high winter or spring moisture.

Historically, the cool shrub PVG existed primarily in east-central and extreme southeast Oregon, southwest Idaho, and extreme northeast Nevada (map 3.11). Comparable areas listed in table 3.38 are climate divisions Oregon South Central, Oregon Southeast, Idaho Southwest Highlands, and Nevada Northeast, of which the cool shrub PVG constitutes a high percentage of only the Idaho Southwest Highlands climate division. For this climate division, about 17 centimeters of precipitation is received during the winter-spring period. Drought years, in which less than 75 percent of the winter-spring precipitation is received, occurred 20 percent of the time in this area. Conversely, relatively wet periods, characterized by two or more successive years of greater than 110 percent of the winter-spring precipitation, were documented nine times in the 100-year period from 1895-1994. In general then, drought frequency and above-normal precipitation frequency were similar for the cool shrub and dry shrub PVGs.

Most of the dominant shrub, grass, and forb species have adapted to a cool-season moisture regime. The herb and shrub species are highly dependent upon soil moisture stored from spring rains and winter precipitation. The majority of their growth and reproduction occurs during the spring and summer. The cool-season species typically become dormant in the late summer and early fall, but also can become active in response to fall rains or early snow melts.

Soil characteristics of the cool shrub PVG generally indicate that they developed with mixed-shrub and grassland potential vegetation. When these sites are invaded by trees, the trees often become very dense and therefore, highly stressed during the summer. Stressed trees are commonly attacked by defoliators or beetles, creating areas with high fuel loadings of decadent wood and fine-flammable foliage. Trees generally tie up nitrogen and other trace nutrients, decreasing the overall site productivity. Foliage cover and basal cover of shrubs, grasses, and forbs eventually all but disappear from these sites. Deep litter and duff layers from conifer foliage then accumulate. Fires in these cool shrub PVGs can be of very high intensity during drought years, leaving few post-burn perennials to revegetate the site.

In general, the native system was dominated by a mosaic of upland shrubland and upland herbland physiognomic types (table 3.41). During some temporal cycles, sites could have been dominated by extensive areas of either upland shrubland or upland herbland physiognomic types, depending on the length of the fire-return interval. Areas dominated by uniform distributions of upland shrubs or trees (75% of the cool shrub PVG area) typically burned with lethal fires. Lethal fires typically killed the shrubs or trees and stimulated established forbs during the year following a disturbance. Burned sites were then dominated by established grasses. In small patches containing high amounts of decadent or dead shrubs, decadent grasses, and high accumulations of litter, fires often killed the existing perennial grasses and forbs, creating small openings for early-seral forbs. Regeneration of shrubs or trees was generally killed by drought or fire. Lethal fires had intervals of about 25 to 75 years. Approximately 10 percent of the cool shrub PVG burned with a mixed-fire regime that created a mosaic of upland herbland and upland shrubland structures. The mixed-fire intervals were similar to those of lethal fires. Approximately 10 to 15 percent of the cool shrub PVG burned with non-lethal fires, generally as reburns of the upland herbland physiognomic type. Non-lethal fire intervals were generally 15 to 25 years. The fire season was long, generally starting in April or May and extending into October.

Historically, the early-, mid-, and late-seral woodland physiognomic types generally occupied from 3 to 10 percent of the cool shrub PVG. The upland herbland physiognomic type ranged from 10 to 40 percent, depending on the temporal period of the fire cycle. Conversely, the composition of the upland shrubland physiognomic type ranged from 60 to 80 percent. We believe that exotic species would eventually dominate at least 2 percent of the PVG. The cool shrub PVG is susceptible to invasion by exotic weed species such as knapweed, leafy spurge (*Euphorbia esula*), and perennial grasses such as Kentucky bluegrass (*Poa pratensis*).

The native grazing regime within the cool shrub PVG was similar to regimes in the dry grass and dry shrub PVGs. However, cool shrublands were generally not strongly influenced by winter grazing in the historical period.

The composition of physiognomic types within the cool shrub PVG has changed since the implementation of fire suppression and livestock grazing, the invasion of exotics, and the conversion to agricultural uses (table 3.41). The similarity of physiognomic type composition between historical and current periods was 76 and 89 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). The current period areal extent of woodland physiognomic types increased to 25 to 30 percent of this PVG, and the upland herbland physiognomic type was nearly eliminated. Two-thirds of the current period PVG was dominated by upland shrubland physiognomic type. Exotics plants were common components of the upland shrubland physiognomic type. Species composition and structure within the upland shrubland stage changed as a result of heavy, early-season or season-long livestock grazing. Large dominant bunchgrasses were generally replaced by smaller bunchgrasses, Kentucky bluegrass, native forbs, exotic forbs, and seeded exotic grasses such as bromes and timothy (*Phleum pratense*).

As with the dry grass and dry shrub PVGs, the highest departures from the biophysical template occurred in those areas subjected to high levels of continuous season-long or early-season grazing that were also heavily roaded. Due to a high component of decadent upland shrubland and woodland physiognomic types in the cool shrub PVG, the current period fire regime was dominated by lethal fires occurring at 25- to 75-year intervals. When woodland encroachment occurred, fuels accumulated and communities exhibited high stress and low foliage moisture. During drought years, very intense fire events had the potential to occur in woodland physiognomic types, and often caused relatively severe effects to the soil surface and mortality to the understory grasses and forbs. Approximately 30 percent of

[3]+ = < 0.5%.

the cool shrub PVG had a mixed-fire regime, which was probably a result of its rough terrain and moderate fuel moisture conditions.

The LAI of the cool shrub PVG did not change substantially between the historical and current periods. Historically, the LAI averaged approximately 2.1 (range = 1.1 to 4.8; sd = 0.4), whereas during the current period, the LAI had a mean of 2.3 (range = 0.2 to 54.9; sd = 2.8). However, the high standard deviation in comparison to the mean for the current period, and the wide range of the values, indicates that the mean could be substantially different from the historical. In addition, the current system could be much less predictable than the historical system.

The effects of departures of succession and disturbance processes in the cool shrub PVG were similar to those reported for the dry grass and dry shrub PVGs. The similarity of fire regime composition between historical and current periods was 62 and 69 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). The similarity of succession/disturbance regimes was comparable with the dry grass and dry shrub PVGs.

Riparian Shrub PVG

Agricultural and urban development were responsible for an 80 percent areal decline of the riparian shrub PVG. Although it was always a relatively minor component of the Basin, the areal extent declined from 2 to 0.5 percent between the historical and current periods (maps 3.11 and 3.12). The distribution of the riparian shrub PVG shifted to higher elevations. Historically, 38 percent occurred above 1,200 meters; whereas in the current period, 79 percent of the riparian shrublands occurred above 1,200 meters (table 3.18). BLM/FS lands contained 55 percent of the current period riparian shrub PVG. We do not anticipate that a substantial amount of riparian shrublands will be converted by agricultural or urban development on Other lands in the future. Consequently, we assume that the areal extent of the riparian shrub PVG will remain relatively constant into the future.

The riparian shrub PVG is not generally limited by moisture, except during late summer and drought years. Water tables are typically too high and soils not adequately aerated to allow tree establishment. Native communities are usually the most diverse of any PVG with a broad mixture of shrub, grass, forb, and sedge species. Production of biomass is high.

Historically, the native system was generally dominated by a mixture of riparian shrubland (60%) and riparian herbland physiognomic types (40%) (table 3.42), depending on the disturbance cycles. Disturbance regimes were dominated by floods, fires, and to a lesser degree, grazing. Flood cycles typically occurred at 20- to 30-year intervals. The fire regime was dominated by non-lethal and mixed fires that occurred at 25- to 50-year intervals. The fire season was relatively short in the riparian shrub PVG, generally starting in August and ending in early September during drought years. Grazing by native ungulates was probably widely scattered during drought years.

The riparian shrub PVG changed between historical and current periods due to fire suppression, livestock grazing, invasion of exotics, and agricultural and urban developments (table 3.42). The similarity of physiognomic type composition between historical and current periods was 47 percent for the Basin as a whole and for BLM/FS lands (table 3.31). Exotic species, such as Canada thistle (*Cirsium arvense*), were common components of most communities within the riparian shrub PVG. In the current period, Kentucky bluegrass dominated at least 1 percent of this PVG. The riparian shrubland physiognomic type had become less dominant, occupying 59 percent of the PVG in the current period. The current period riparian herbland physiognomic type contained a relatively large proportion of exotic plants, and was less productive than it was historically.

Disturbance regimes within the riparian shrub PVG also changed from the historical to the current period. Flood events on larger streams had largely been controlled by dams. Fires also occurred less frequently than they had historically. The similarity of fire regime composition between historical and current periods was 34 and 43 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). We speculate that grazing changed from an extensive, low-intensity regime, to a greater intensity regime in the riparian shrub PVG.

We did not detect a substantial change in the LAI between the historical and current periods. Historically, the LAI averaged approximately 1.5 (range = 1.0 to 7.7; sd = 1.2), whereas during the current period, the LAI averaged 2.2 (range = 0.2 to 13.6; sd = 2.4). The current period high standard deviation relative to the mean and wide range of values indicates a more variable and less predictable system than the historic system.

As with most of the rangeland PVGs, the highest departures from the unaltered biophysical template occurred in those areas subjected to excessive livestock grazing pressure, and were also heavily roaded. The overall departure of

[3]+ = < 0.5%.

succession and disturbance processes in the riparian shrub PVG was high, primarily due to agricultural and urban development, changes in grazing and flooding regimes, and the introduction of exotics. The similarity of succession/disturbance regime composition between historical and current periods was 3 and 12 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). The subsequent effects were similar to those described for most other rangeland PVGs.

Riparian Woodland PVG

The riparian woodland PVG is a relatively rare component of the Basin (1%; maps 3.11 and 3.12). According to our broad-scale data, the riparian woodland PVG did not decline substantially between historical and current periods (table 3.18). However, fine- or mid-scale analysis would suggest that the riparian woodland PVG declined substantially between historical and current periods. This decline was attributable to agricultural

development, urbanization, and invasion by exotic plant species. Thus, our failure to detect broad-scale changes of the riparian woodland PVG warrants further investigation.

The elevational distribution of the riparian woodland PVG did not change substantially; most (98%) occurred above 1,200 meters during the current period, compared with 96 percent in the historical period. Approximately half (54%) of the current period riparian woodland PVG occurred within BLM/FS lands (map 3.12). We do not anticipate substantial future losses of this type attributable to agricultural or urban development on Other lands. Consequently, we assume that the areal extent of riparian woodlands will remain relatively constant into the future.

In general, the riparian woodland PVG is not limited by moisture, except during late summer and drought years. High water tables prevent the establishment of mature coniferous forests. Natural communities are usually highly diverse, with a broad mixture of shrub, grass, forb, and sedge species. Biomass production is relatively high.

The native system was generally dominated by a mixture of riparian shrubland, early-seral forest, and early-, mid-, and late-seral woodland physiognomic types. Historically, the riparian woodland PVG was dominated by mid-seral physiognomic types (60%), followed in dominance by early-seral (20%), riparian shrubland (20%), and late-seral (2%) physiognomic types. Disturbance regimes were historically dominated by flood and fire events, and grazing to a lesser degree. Flood cycles typically occurred on 10- to 20-year intervals. The fire regime was dominated by lethal or mixed fires that occurred on 65- to 150-year intervals. The fire season was relatively short in riparian woodlands, generally starting in August and ending in early September, but only during drought years. Grazing by native ungulates was probably widely scattered and of low intensity. However, some excessive grazing pressure was probably exerted on riparian woodland PVGs during drought years.

Since the historical period, the structure and composition of the riparian woodland PVG has changed due to intensive livestock grazing, the invasion of exotics, and agricultural and urban development (table 3.43). The similarity of physiognomic type composition between historical and current periods was 74 and 85 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). Exotic plants (for example spotted knapweed, Canada thistle, and leafy spurge), were common components of most current period communities within the riparian woodland PVG, and dominated 1 percent of its areal extent. Mid-seral riparian woodland physiognomic types greatly increased and came to dominate approximately 90 percent of the PVG. The areas of all other physiognomic types generally declined from their historical levels. Current period flood events of larger streams were largely controlled by dams. Fires burned less frequently, but more intensively than they did historically. The similarity of fire regime composition between historical and current periods was 71 and 85 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31).

The LAI for the riparian woodland PVG changed substantially between historical and current periods. Historically, the LAI averaged approximately 6.8 (range = 1.0 to 14.4; sd = 2.5), whereas in the current period, the LAI had a mean of 8.4 (range = 0.2 to 32.2; sd = 2.1). The LAI probably increased because, historically, the riparian woodland PVG comprised a larger array of structural stages; whereas, most of the current period PVG comprised mid-seral woodland types. Although the standard deviation did not change appreciably, the increased range indicated a somewhat less predictable system.

As with most other rangeland PVGs, the highest departures from the unaltered biophysical template occurred in those areas subjected to excessive livestock grazing pressure and extensive roading. The overall departure of succession and disturbance processes in the riparian woodland PVG

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

was high due to the changes of grazing and flood regimes, and the introduction of exotic vegetation. The similarity of succession/disturbance regime composition between historical and current periods was 12 and 15 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31). The subsequent effects of these changes were similar to those reported for most other rangeland PVGs.

Alpine PVG

The alpine PVG occurs above 1,200 meters elevation. The areal extent of the alpine PVG did not change substantially between historical and current periods (table 3.18). Most (83%) of the alpine PVG occurred on BLM/FS lands (maps 3.11 and 3.12).

The alpine PVG is limited by a short growing season. The moisture regime ranges from dry to wet. Native communities are very diverse with a large set of low shrubs, sedges, forbs, and grasses that are adapted to alpine environments.

The alpine PVG rarely burns. When fires do occur, they are usually limited to small patches and are generally non-lethal. Fire-return intervals are long. The native grazing regime probably is characterized by scattered low-intensity, seasonal use by native ungulates.

We did not detect any major broad-scale changes of physiognomic types within the alpine PVG between the historical and current periods (table 3.31), possibly due to the resolution of our broad-scale data. Similarly, no substantial changes of fire regime occurred within the alpine PVG. Based on review of finer-scale information, we suspect that excessive grazing pressure by domestic sheep caused changes in plant communities and soil conditions.

Broad-scale departures of succession and disturbance processes in the alpine PVG were low. Those effects that we suspect had occurred should be evaluated with a fine-scale assessment in a future investigation. The similarity of succession/disturbance regime composition between historical and current periods was 11 and 14 percent for the Basin as a whole and for BLM/FS lands, respectively (table 3.31).

Water PVG

The water PVG is nearly evenly distributed above (48%) and below (52%) 1,200 meters elevation. We did not detect any measurable changes in the water PVG between historical and current periods (table 3.18), largely because of the resolution of our data. Although, we know that many large impoundments were developed within the Basin, we also suspect that many large water bodies declined in size due to anthropogenic uses. However, finer resolution data are necessary to evaluate such changes. Approximately 18 percent of the water PVG occurred on BLM/FS lands.

Rock PVG

Most of the rock PVG occurs above 1,200 meters elevation. We did not detect any changeof the areal extent of the rock PVG between the historical and current periods (table 3.18). Nearly all of the rock PVG (96%) occurred on BLM/FS lands.

Agricultural PVG

Most (75%) of the agricultural PVG occurs below 1,200 meters, and virtually all of it occurs on Other lands (table 3.18). The agricultural PVG is not native to the Basin and did not exist historically. Its development resulted in the decline of many of the native PVGs, particularly the dry grass, dry shrub, and riparian shrub PVGs (maps 3.11 and 3.12).

In general, the LAI of the agricultural PVG was relatively high (mean = 2.3; range = 1.0 to 3.4; sd = 0.5). The LAI was similar to the LAIs of the dry grass and dry shrub PVGs. Although structures of agricultural hayland and pasture were similar to some of the native systems that they replaced, the grazing and haying disturbance regimes generally displaced most native species.

Urban PVG

Most (81%) of the urban PVG was developed at elevations below 1,200 meters elevation, and was derived primarily from the dry grass, dry shrub, and riparian shrub PVGs (table 3.18). The urban PVG is located entirely within Other lands.

Road PVG

The road PVG is an extensive cultural development and occurs as linear features. Although roads are designed to function as connective linkages for humans, they also serve as travel ways for other animals, and have facilitated the dispersal of exotic plants. In addition, they have functioned as conduits for water flow (in ditches) and sediment transport. Well-maintained roads (fitted to the land), with minimal cut and fill slopes, good drainage features, and vegetation cover in ditches and on cut/fill slopes are generally not a problem in terms of bare soil, erosion, and sediment transport. However, many of the forest and rangeland roads located in the Basin were not well maintained, had large cut and fill slopes, poor drainage features, and lacked vegetation cover in ditches and on cut/fill slopes. Many of the roads were surfaced with fine aggregate or native materials that are easily eroded. Their high erosion potential, in conjunction with their ability to capture and transport water, has created an effective sediment transport systems. In addition, the higher densities of roads often occur in watersheds that are sensitive to soil erosion.

The current road PVG exists on approximately 1.9 percent of the Basin (table 3.19). The distribution of the road PVG is slightly skewed towards Other land ownerships (2.1%) as compared to BLM/FS lands (1.7%). Approximately 39 percent of all roads in the Basin are located in highly sensitive watersheds in terms of their susceptibility to erosion and sediment transport. Another 22 and 39 percent of all roads are located in watersheds that have moderate or low erosion, and sediment transport sensitivity, respectively. There is little doubt that problems relative to sedimentation in streams are highly correlated to the large proportion of roads that occur in high sensitivity watersheds.

Many opportunities exist to restore or redesign existing roads and to avoid the development of new roads in moderate and high sensitivity watersheds. In addition, finer-resolution data could be used to (1) orient transportation systems to the less-sensitive land types within watersheds, (2) reduce cut/fill slopes, (3) improve the selection of surfacing material, and (4) better design drainage systems.

Comparison of Biogeochemical Processes and Succession/ Disturbance Regimes

Each PVG has a unique combination of biogeochemical processes, seasonal climates, and topoedaphic conditions that produce a complex of succession and disturbance regimes (table 3.44). The NPP, NAI, CSI, and WSI values shown in table 3.44 are historical values without the influence of management actions except for agriculture and roads, which were new PVGs developed by humans. The seasonal climate gradient index (SCI) and topoedaphic index (TEI) did not change unless climate or land-forming changes occurred. The SCI and TEI also accounted for landscape continuity that influences disturbances across space. As discussed previously in the "Relationships to succession/disturbance regimes" subsection of this "Results and Discussion" section, the NPP, NAI, CSI, and WSI have changed as a result of changed succession and disturbance regimes.

We determined that current succession/disturbance regimes could be spatially predicted based on PVGs, native succession/disturbance regimes, and recent management and disturbance histories. Thus, this information provides a way of stratifying

Table 3.44—Trends of relativized biogeochemical characteristics of potential vegetation groups (PVGs) and relationships with succession / disturbance regimes (SDR[1]).

[1]See table 3.6 for description of succession/disturbance regime cycles.

[2]Seasonal climate gradient—index of spring-to-summer evapotranspiration gradient. High values indicate steep gradients that result in high stress, and high risk of very dry fuels.

[3]Topoedaphic index—index of topographic and soil complexity. High values indicate complex terrain and potential for complex fire weather and fuel conditions.

[4]NA = Not Applicable; AC = Accelerated cycle; LC = Long cycle; SC = Short cycle; VC = Very long cycle; FM = Frequent maintenance; IM = Irregular maintenance; MC = Moderate cycle; RC = Retrogressive cycle.

[5]Not present historically—calculated for current.

[6]Trend—trend from historical to current: +=increase; -=decrease; NC=no change.

[7]+ = Increasing trend from historical to current period conditions.

[8] – = Decreasing trend from historical to current period conditions.

[9]NC = No trend from historical to current period conditions.

environments and disturbances at multiple-spatial and temporal scales, without requiring a current period vegetation map that would require continual updating. Management prescriptions designed to achieve a desired succession/disturbance regime for a given PVG-succession/disturbance regime condition could then be developed to meet management objectives. This set of prescriptions could be used for project planning or implementation that would contribute to coarser-scale, desired conditions, as well as meeting finer-scale objectives. The PVG, succession/disturbance regimes and prescriptions provide a template that is useful for the long term, as compared to current period vegetation maps which would change every few years as a result of succession and disturbance. In addition, this information provides an ecological and landscape systems approach to understanding vegetation and disturbance processes and potential response. Another valuable asset of knowing the PVG, succession regime, and management and disturbance histories is that the current vegetation could be predicted with much higher precision from satellite imagery, photo interpretation, or ground-truth extrapolation.

The woodland PVG had high NPP and NAI, and moderate WSI. This was combined with a steep seasonal gradient (from moist winter to dry summer conditions) on typically rocky upland foothills that produced a complex of succession/disturbance regimes dominated by moderate cycle- and irregular-maintenance regimes (table 3.6). Fire exclusion, excessive livestock grazing pressure, and invasion of exotics, in conjunction with succession to later vegetation stages, altered the composition of succession/disturbance regimes to one dominated by retrogressive and long-cycle regimes. Associated changes of biogeochemical characteristics included increased NPP and NAI, decreased CSI, and increased WSI. Fire exclusion, as a result of fire-control efforts plus grazing of fine fuels, resulted in an increase of woodland trees and shrubs compared to herbs. The tree and shrub species had higher leaf area and thus, the associated increase of NPP. However, in these moisture-limited environments, the higher leaf area caused increased water stress. Increased temperatures in the understory resulted in increased decomposition and nutrient availability, and susceptibility to erosion. Total loading of carbon relative to growth potential, as indicated by the CSI, decreased as a result of herbaceous cover loss.

The dry forest had high NPP, moderate NAI, and high carbon and water stresses. The seasonal gradient from moist winter to dry summer conditions was steep and topoedaphic conditions were generally moderate on plains, break, foothill, and some mountain landforms. These conditions produced an inherent succession/disturbance regime that was dominated by a complex of frequent-maintenance and moderate-cycle regimes. Fire exclusion and timber harvest of large, shade-intolerant, and fire-, insect-, and disease-resistant trees shifted the dry forest succession regime to one dominated by a complex of long- and retrogressive-cycle regimes. These changes caused an increase in NPP and NAI with associated increases in carbon and water stresses.

The moist and cold forest PVGs had similar biogeochemical relationships. Both had high NPP and CSI with moderate WSI. They differed in that NAI was moderate in the cold forest, while it was high in the moist forest. Both PVGs had high seasonal gradients from moist-to-wet winters, to dry summers. Both generally occurred on moderate topoedaphic conditions. However, the cold forest PVG generally occurred in mountain landforms, while the moist forest PVG occurred across both foothill and mountain landforms. The dominant environmental difference between the two PVGs

was a shorter growing season and colder temperatures in the cold forest, which affected nutrient availability and precluded growth of many moist forest tree, shrub, and herb species because they are ill-adapted to cold temperatures.

The moist and cold forest PVGs had inherent succession/disturbance systems that were dominated by a complex of accelerated-cycle and irregular-maintenance regimes. Both were substantially affected by the introduction of blister rust, which nearly eliminated the dominant seral tree species from each system (that is, the western white pine in the moist forest, and whitebark pine in the cold forest). Both were also affected by fire exclusion, although the temporal effects occurred much faster in the moist forest than in the cold forest. However, the trends were very similar. The moist forest PVG was substantially affected by traditional timber-harvest activities that did not simulate the native succession/disturbance regime. Timber harvest affected the cold forest to some extent in the Cascade Mountains, but not substantially in the Rocky Mountains. Blister rust, fire exclusion, and timber harvests changed the composition of succession/disturbance regimes to a complex dominated by moderate- and retrogressive-cycles in the moist forest, and long- and retrogressive-cycles in the cold forest.

The trends in biogeochemical variables for the cold forest were quite different with an increase in NPP and NAI, as compared to a decrease in the moist forest. The increase in NPP and NAI was due to the transition to shade-tolerant species in the cold forest [such as subalpine fir (*Abies lasiocarpa*)] that tended to photosynthesize at higher rates; an increase in dead wood and nutrient release in areas of high whitebark pine mortality; and increased levels of finer woody fuels that were more rapidly cycled into nutrients. Carbon stress declined due to the lack of late-seral stage development, which in turn was the result of the decline in shade-intolerant species. In contrast, NPP and NAI declined in the moist forest PVG. Tree and shrub species that dominated this type in the current period generally had lower NPP, and nutrients were cycled at slower rates. As a result of higher accumulations of biomass in mid-seral stages, carbon and water stress increased.

The dry grass, dry shrub, and cool shrub PVGs had a similar set of biogeochemical characteristics. These non-forest (rangeland) PVGs differed from forest PVGs (for example, woodland, dry forest, moist forest, and cold forest) in that they had high water stress, moderate carbon stress, high nutrient availability, and moderate net primary productivity. In contrast, the forest PVGs had lower water stress, higher carbon stress, lower nutrient availability, and higher net primary productivity. The woodland and dry forest PVGs were transitional, falling between the non-forest and moist forest PVGs. The primary factor distinguishing the woodland PVG from non-forest PVGs was its higher carbon stress and topoedaphic conditions. The primary factors distinguishing the woodland PVG from the dry forest PVG were its lower NPP, lower carbon stress, and topoedaphic conditions. The dry forest PVG had higher NPP, lower NAI, and higher CSI, relative to the non-forest PVGs.

The primary difference between the dry grass, and dry or cool shrub PVGs was the seasonal climate gradient, which was higher for the dry and cool shrub PVGs, than the dry grass PVG. The dry grass PVG generally occurred in climates with little winter and spring sunlight, and relatively lower spring evaporation and winter sublimation rates relative to the shrub PVG. Available moisture was often influenced by topoedaphic conditions, such as those found on the Columbia Plateau, where deep loess soils retain winter moisture in the surface horizon that is critical for summer growth.

The dry grass, dry shrub, and cool shrub PVGs had an inherent succession/disturbance system that was dominated by a complex of moderate-cycle and frequent-maintenance regimes. This was substantially changed by a history of fire exclusion, (late 1800s through current) excessive growing-season grazing by livestock that selectively grazed the dominant perennial grasses, and the invasion of exotic forbs and annual grasses. The composition of the succession/disturbance regime shifted to a system dominated by retrogressive-, and moderate- to long-cycle regimes, with substantial amounts of the short-cycle regime in areas that had an understory of, or were dominated by, exotic annual grasses.

The riparian system was complex and dynamic with variations from herb, to shrub, to woodland-dominated systems. The riparian system could be distinguished from the forest and non-forest PVGs because of its topoedaphic conditions, which maintained higher levels of moisture in the growing season. Higher moisture levels promoted high levels of NPP and NAI, while maintaining fairly low carbon stress, in environments that normally had steep winter-to-summer moisture gradients. This resulted in a brief period of high WSI during summer drought. The native succession/disturbance regime was dominated by a complex of long- and moderate-cycle regimes. As a result of fire exclusion, extensive growing-season grazing by livestock that selectively grazed the woody plants and perennial grasses, and the invasion of exotic forbs and grasses, the composition of the succession/disturbance regime shifted to one dominated by a complex of retrogressive- and long-cycle regimes. Our simulations of NPP indicated a decrease in the shrub types due to the loss of shrub cover, and an increase in the riparian woodland types due to a shift from broadleaf to conifer and an increase in tree density. In association, carbon and water stress increased, while nutrient availability declined in the shrub type. In contrast, carbon stress declined in the woodland types as a result of an overall reduction of total biomass, while water stress and nutrient availability increased.

The alpine PVG differed substantially from all other PVGs. As a consequence of low temperature and high precipitation levels, the alpine PVG had a relatively low NPP, NAI, CSI, and WSI. Historically, this system was dominated by a long-cycle regime. Due to fire exclusion, this system shifted to a complex of very long- and long-cycling regimes.

Agricultural lands were not present in the native system, but there were inherent biogeochemical processes based on the changed conditions. Because of inputs of water, fertilizer, crop species, tillage, and weed control, the NPP and NAI could be maintained at relatively high levels with moderate carbon stress and high water stress. The succession/disturbance regime was dominated by the short-cycle regime due to tillage and production of annual crops, or perennial crops that lasted 3 to 5 years. In comparison to the original potentials the trends of NPP, CSI, and WSI increased, while NAI declined.

The road PVG shifted from the succession/disturbance regime of the original PVG to a short-cycle system. NPP, NAI, CSI, and WSI all declined as the result of loss of vegetation cover.

Ecological Reporting Units

This subsection provides a description by ERU of the trends in potential vegetation group composition, vegetation succession, and disturbance dynamics from the historical to the current period. Furthermore, we highlighted the abiotic factors such as geology, hydrology, climate, and soil, that affected trends. The data for this subsection were derived from the assessment of current conditions and the 100-year simulation of historical conditions used to estimate historical range of variability (HRV). The PVGs, vegetation, succession, and disturbance dynamics of the ERUs were associated with differences in geomorphology, landform, soil, climate, and history of human use. The geologic, hydrologic, climatic, and soil features associated with each ERU have been described in Chapter 2, Biophysical Environments. In following subsections of this "Results and Discussion" section, descriptions and discussions of each ERU are oriented around the dominant PVGs, their compositional changes of physiognomic types in relation to their HRV, and the associated implications to succession/disturbance regimes. Dominant PVGs were selected based on those that composed at least 5 percent of the BLM/FS lands during the current period. In the final part of this subsection, we provide a comparison among ERUs relative to biogeochemical processes and succession/disturbance regimes.

There were substantial differences among ERUs in the composition of the PVGs. We summarized the areal extent of woodland, dry forest, moist forest, cold forest, dry grass, dry shrub, and cool shrub PVGs in the ERUs by All land ownerships, BLM/FS land ownerships, and Other land ownerships (table 3.45).

Blue Mountains ERU

The Blue Mountains ERU is located primarily in northeastern Oregon and southeastern Washington. A small portion of this ERU also occurs in central Idaho (map 3.3). This ERU has relatively low relief (160 to 2,900 m), and exists as a complex of foothills and mountains resulting from the erosion of volcanic parent material (map 3.17). Extensive areas of soils in this ERU were susceptible to erosion by wind, and shrinking and swelling from drying or wetting (table 3.46; maps 3.18, 3.19, and 3.20). Landforms include a mix of foothills, breaks, mountains, and valleys that form a complex of headwater and downstream (mainstem) watersheds (map 3.21). The number of headwater watersheds found in an ERU, compared to the number of downstream watersheds, is important because ERUs with more area in headwater systems are less subject to invasion by exotic plants and animals, in both terrestrial and aquatic environments. The Blue Mountains ERU is primarily situated in ecoregion section M332G (map 3.1).

Precipitation in the Blue Mountain ERU averages 55 centimeters per year (range = 29 to 120 cm). Climate was strongly influenced by oceanic storms from the west. Most of the precipitation occurred in the form of winter snows or spring rains. A steep moisture gradient existed between the relatively moist spring conditions and the very dry summer and fall conditions. The growing season was relatively long, vegetation was diverse, and the biogeochemical energy relationships were dynamic. Consequently, the Blue Mountains ERU had an inherently high rate of NPP and nutrient cycling, which was associated with high carbon and water stress in the upland areas.

[1]Climate indicators include: (H) high susceptibility to management-induced disturbance stress = less than 25 centimeters annual precipitation zone; (M) moderate susceptibility to management-induced disturbance stresses = 25 to 30 centimeters annual precipitation zone; and (M-L) moderate to low susceptibility to management-induced disturbance stresses) = greater than 30 centimeters annual precipitation zone. The amounts indicated represent the percent of the ERU found within each of those climate zones depending on land ownership category.

[2]Soil property indicator codes and definitions: SEW = Soil erodibility to water; SAL = Soil salinity; WE = Soil erodibility to wind; SSP = Potential for soil to shrink or swell from drying or wetting; and SAR = Soil sodicity. Percent of ERU in each soil property indicator, when summed across a row [that is, across the 13 individual or combination soil property indicator(s)], will be less than or equal to the percent of ERU in the climate (precipitation zone) indicator.

[3]T = Trace; less than or equal to 0.50%.

[4] - = Not Applicable. Soil map units that contained 75 percent or greater areal extent of soils characterized by individual or combination soil property indicator(s) did not exist in this ERU in the precipitation zone associated with the susceptibility rating.

[5]Climate (precipitation) data for the Snake Headwaters ERU were not available for approximately 2 percent of the ERU. Some of the lands without available precipitation data included soil map units that were characterized by soil erodibility to wind (approximately 1 percent of the ERU).

[6] In the All Lands ownership category, the percent of ERU found in the 3 climate (precipitation) zones should sum to 100, with only slight deviations due to rounding error.

Map 3.18—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil erodibility to wind. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils that are characterized by wind erodibility Groups 1 through 3; none of the other four, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Map 3.19—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with potential for soil to shrink or swell from drying or wetting, and soil erodibility to wind. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having these specific soil-property indicators: a high shrink-swell potential (SSP), and wind erodibility Groups 1 through 3; none of the other three, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Map 3.20—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with potential for soil to shrink or swell from drying or wetting. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having a high shrink-swell potential (SSP); none of the other four, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Map 3.21—Headwater and downstream general landforms. This map shows the dominant landforms for subwatersheds that lie at headwaters, or are in down-river or downstream locations within the Basin. Headwater and mountainous subwatersheds are often less vulnerable to the detrimental effects associated with the spread of exotic biota and anthropogenic-induced erosion. In contrast, they are often more vulnerable to upslope spread of wildfire.

Substantial changes in fire regimes occurred in the Blue Mountains ERU as a result of fire exclusion, timber harvest practices, and the invasion of annual grasses in the dry shrub and dry grass PVGs (maps 3.22 and 3.23) Fire severity generally shifted from non-lethal and mixed, to lethal in the forest PVGs due to longer fire intervals and harvest activities, which did not simulate the composition and structure of the native systems. In the non-forest (rangeland) PVGs, fire severity generally shifted from non-lethal to lethal, and intervals between fires increased due to fire exclusion, closure of shrub canopies, and conifer encroachment.

From a regional-scale perspective, although the Blue Mountains ERU has a negligible amount of area that received less than 30 centimeters of annual precipitation (map 3.24), drought years were documented 12 percent of the time between 1895 and 1994 (table 3.38; climate division: Oregon Northeast). This level of drought is less than other ERUs that have higher arid, non-forest PVG dominance. Consequently, most of the non-forest PVGs that have been affected by the invasion of exotics or by excessive livestock grazing pressure have a fairly high potential for restoration. However, at the landscape scale 16 percent of the area consists of steep break and valley landforms with southerly exposures and microclimates that are conducive to droughts.

There has been a long history of livestock grazing on public lands in the Blue Mountains ERU (map 3.25). Most of the public land has been grazed since the 1860s (Skovlin and Thomas 1995). Improvements in range conditions and associated watershed conditions has occurred since the mid-1900s. However, native vegetation diversity in the non-forest PVGs and the dry forest PVG, which together composed 82 percent of the BLM/FS lands, has been threatened by the invasion of annual grasses and other exotic plants. Cheatgrass, medusahead (*Taeniatherum caput-medusae*), and yellow starthistle (*Centaurea solstitialis*), for example, were three problematic exotic plant species in the Blue Mountains ERU. Approximately 32 and 6 percent of the BLM/FS lands were highly susceptible to invasion by cheatgrass and yellow starthistle, respectively. Roughly 34 and 22 percent of All lands in the Blue Mountains ERU were of high susceptibility to invasion by cheatgrass and yellow starthistle, respectively (table 3.47; maps 3.26 and 3.27). In addition, the prevalence of soils that will shrink or swell from drying or wetting (maps 3.19 and 3.20) enhance the establishment of medusahead, because medusahead shows an affinity for soils with a high clay content.

Road densities in the Blue Mountains ERU are relatively high (map 3.28). At the regional scale, the high road densities typically occur on watersheds with higher sensitivity to disruption of the hydrologic regime (map 3.29). Relative to non-forest watersheds, forested watersheds are generally steeper with less developed soils, and hence are more susceptible to erosion and sediment transport via road networks. Where forested watersheds have been developed for timber harvest, road densities are commonly high. Roads in forested watersheds are typically surfaced with gravel or native materials that are susceptible to sediment transport. Annual grading of these roads maintains a high component of fine material on the road surface, and grades materials into the ditches. Due to continual disturbance, ditches commonly do not develop a vegetation cover capable of filtering sediment.

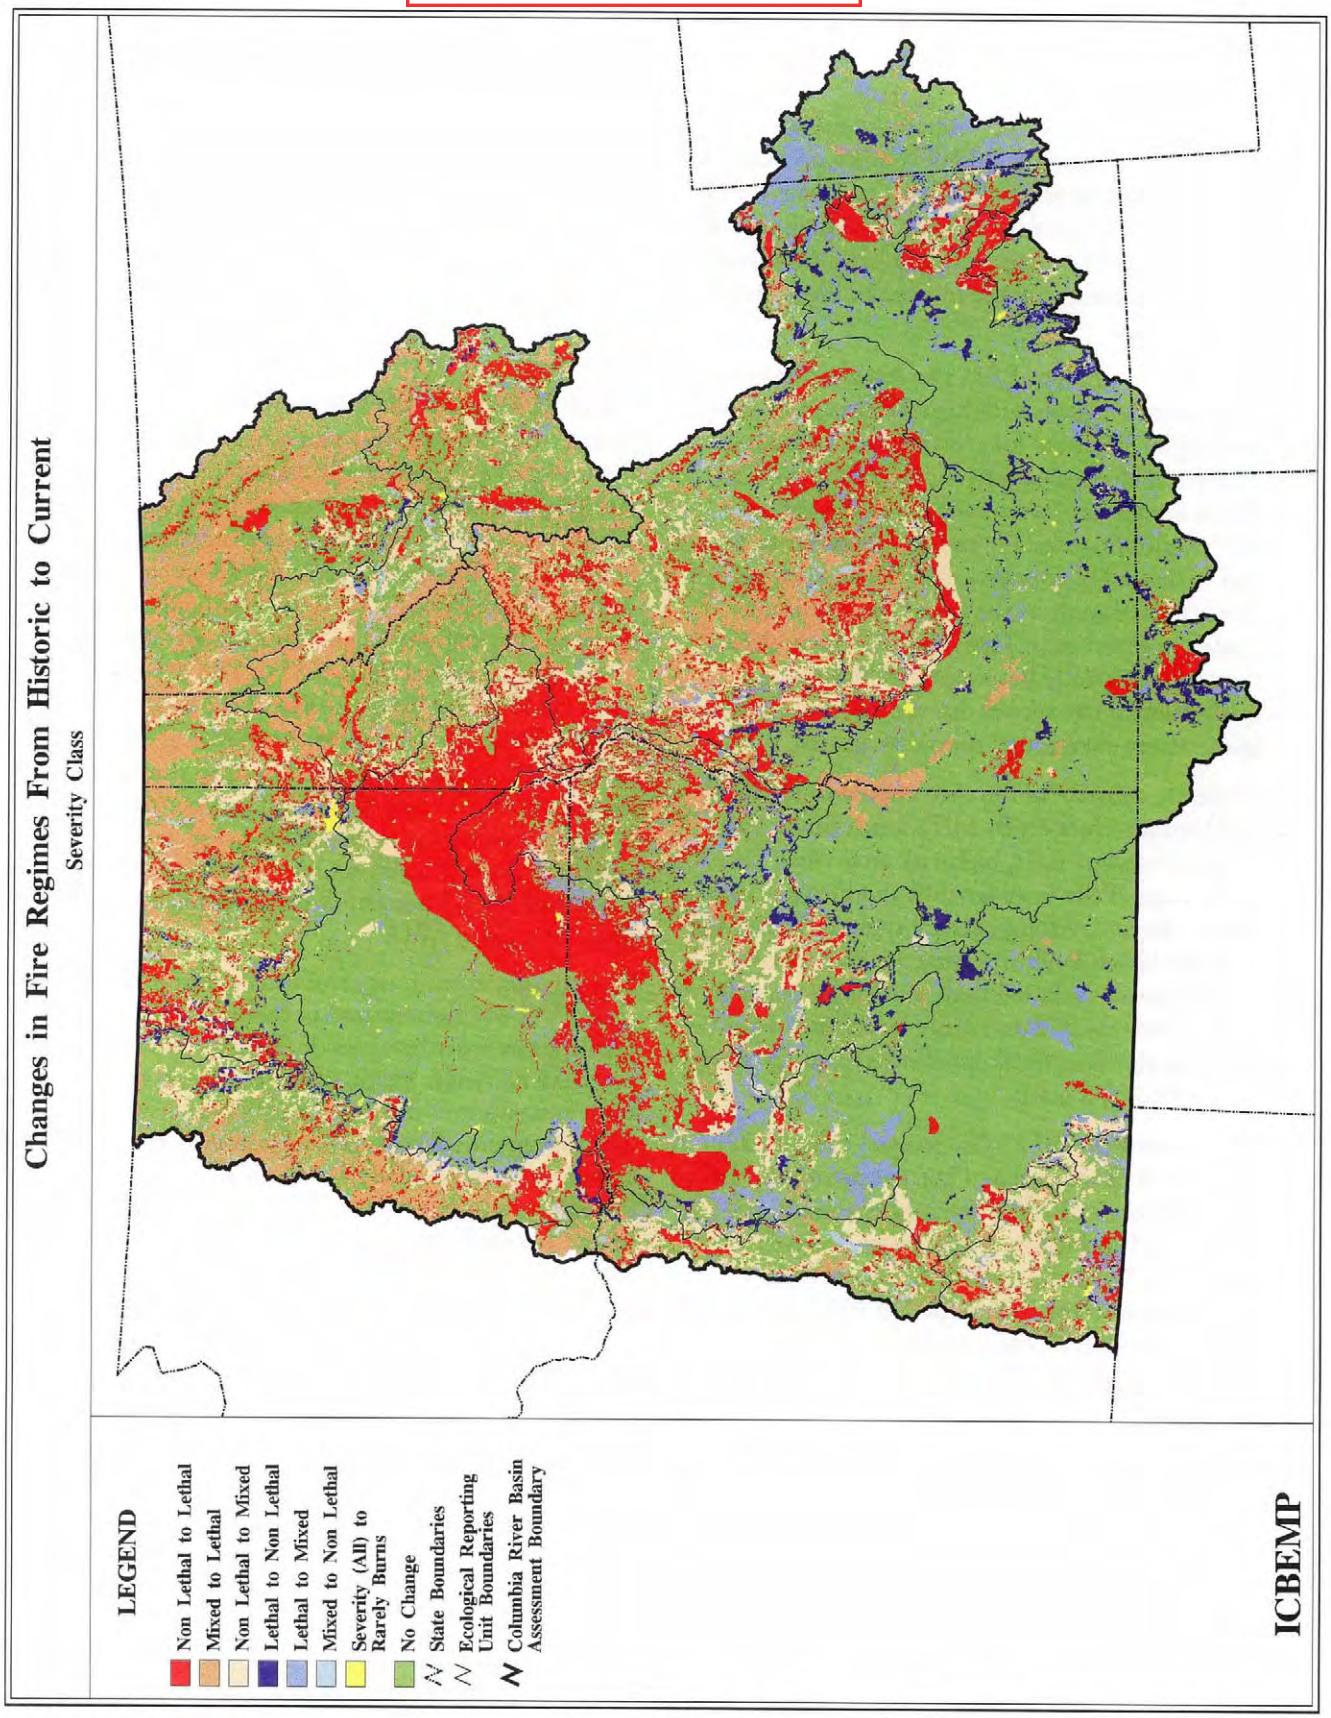
The ownership pattern of BLM/FS and Other lands is relatively fragmented in the Blue Mountains ERU (map 3.30, see glossary for description of land ownership classes). Only the inner core of mountain ridges contain uniform BLM/FS land ownership. Most of the area is mixed, or a mosaic of BLM/FS and Other land ownerships interspersed with uniform BLM/FS ownerships. Much of the BLM/FS lands have high or moderate risk of fire occurrence and associated high-intensity wildfires that would be difficult to suppress (map 3.31). The risk is related to high wildfire occurrence

from both lightning and human-caused ignitions, generally dry summer and fall conditions, and a large component of woody fuels that create the potential for severe fire behavior. The high rate of human-caused fires has generally been associated with high recreational use in areas of higher road densities.

The Blue Mountains ERU also has a substantial component of forests with high fuel accumulations, and higher potential for crown fires, forest insects, diseases, and stress-related mortalities (map 3.32). These forests have an inherently higher rate of NPP, high potentials for carbon and water stress, and witnessed historical timber harvest practices that removed most of the large, stress-resistant, shade-intolerant trees. These large, shade-intolerant trees have generally been replaced by smaller, shade-tolerant tree species that are more susceptible to the above-mentioned mortality agents.

There are substantial fire risks related to the rural/wildland interface on BLM/FS lands (map 3.33). At the landscape scale, high-risk areas often occur at the edge of the steep foothill and break environments. Rural developments are typically associated with the bench landforms that are on the edge of, or interspersed with, the steep, complex topography of the lower foothill and break landforms. The lower foothill and break landforms typically occur on the BLM/FS lands.

The composition of PVGs changed substantially between the historical and current periods in the Blue Mountains ERU, primarily as a result of agricultural and urban development (maps 3.11 and 3.12). We compared the historical PVG composition to the current period PVG composition for BLM/FS, Other, and All land ownerships (table 3.48). Across All ownerships, the historical and current compositions were dominated by the dry forest PVG (47 and 46%, respectively), with fairly even amounts of moist forest, cold forest, dry shrub, and cool shrub PVGs. The historical dry grass PVG areal extent was twice that of the current period on All lands. A substantial amount of the ERU (18%) had been developed for agricultural use. Most agricultural lands were converted from the dry grass, dry shrub, and cool shrub PVGs, with a minor amount from the dry forest PVG. Approximately 2.8 percent of the Blue Mountains ERU was converted to roads.



For BLM/FS lands, the historical and current period compositions were also dominated by the dry forest PVG (31%), with even amounts of moist forest, cold forest, dry grass, dry shrub, and cool shrub PVGs (4-5% each). During the current period, BLM/FS roads constituted 1.6 percent of the Blue Mountains ERU. For Other land ownerships, the current period composition was dominated by agricultural lands (18%). The dry forest PVG made up a substantial area of the Other ownerships (16 and 15% for the historical and current periods, respectively). The areal extent of the dry shrub and cool shrub PVGs declined by nearly 50 percent between the historical and current periods. Roads on Other land ownerships accounted for 1.3 percent of the land area in the Blue Mountains ERU.

The physiognomic type composition of the dry grass PVG was summarized in table 3.49. Exotic herblands were furthest outside the HRV, especially on BLM/FS lands. Exotic plants that were especially invasive into the dry grass PVG within the Blue Mountains ERU included yellow starthistle and cheatgrass. As with all PVGs and all ERUs, the areal extent of exotic herblands in the current period was underestimated, particularly on Other lands. Most other physiognomic types in the current dry grass PVG had areas that were within or close to the simulated HRV. However, woodland development in the current period appeared to be below the HRV on BLM/FS ownerships, and above the HRV on Other ownerships.

Map 3.22—Changes in fire regime severity class from the historical to the current period. Fire severity classes include (1) the lethal regimes, which remove (cycle) the upper vegetation layer, (2) the non-lethal regimes, which maintain the vegetation structure, and (3) the mixed regimes, which are a fine-scale mosaic of lethal and non-lethal. Fire severity class changes were used as indicators for ecological integrity, landscape patterns, and succession/disturbance regimes.

Map 3.23—Changes in fire regime frequency class from the historical to the current period. A change to a less-frequent fire class in forests infers higher levels of fuel accumulation and is usually caused by fire exclusion. A change to a less-frequent fire class in rangelands is often caused by grazing of fine fuels and fire exclusion. Fire frequency class changes were used as indicators for ecological integrity, landscape patterns, and succession/disturbance regimes.

Map 3.24—Annual average precipitation in the Basin, from PRISM data, showing areas (typically rangelands) that receive various increments of precipitation less than 12 inches (<305 mm) and areas that receive greater than 12 inches (>305 mm). Precipitation data were used in the development of the maps showing susceptibility status of the Basin to invasion by exotic plants, and the rangeland health susceptibility to management-induced disturbance stresses.

Map 3.25—The extent of grazing allotments on most public (BLM/FS, State, and other Federal) lands in the Basin. Grazing allotment distributions and associated information were used as a general indicator of potential for excessive livestock grazing pressure effects during the early historical period and subsequent trends in the recent historical and current periods.

Table. 3.47—Percent of each Ecological Reporting Unit (ERU) in the context of All land ownerships, and percent of BLM/FS land ownerships in each ERU, which are contained within the high, moderate, low, and none susceptibility to invasion categories (that is, for five problematic exotic plants within the Basin). Percentages in the high, moderate, and low susceptibility to invasion categories are derived from a Susceptibility to Invasion Index of 38 broad-scale cover types in the Basin (see table 3.174) that lie within the known precipitation range of the exotic plant species. Percentages in the none susceptibility category represent lands that (1) lie outside the known precipitation range of the exotic plant species, (2) are cover types with unknown susceptibility, or (3) are cover types not included in this analysis (that is, the barren, water, and urban cover types).

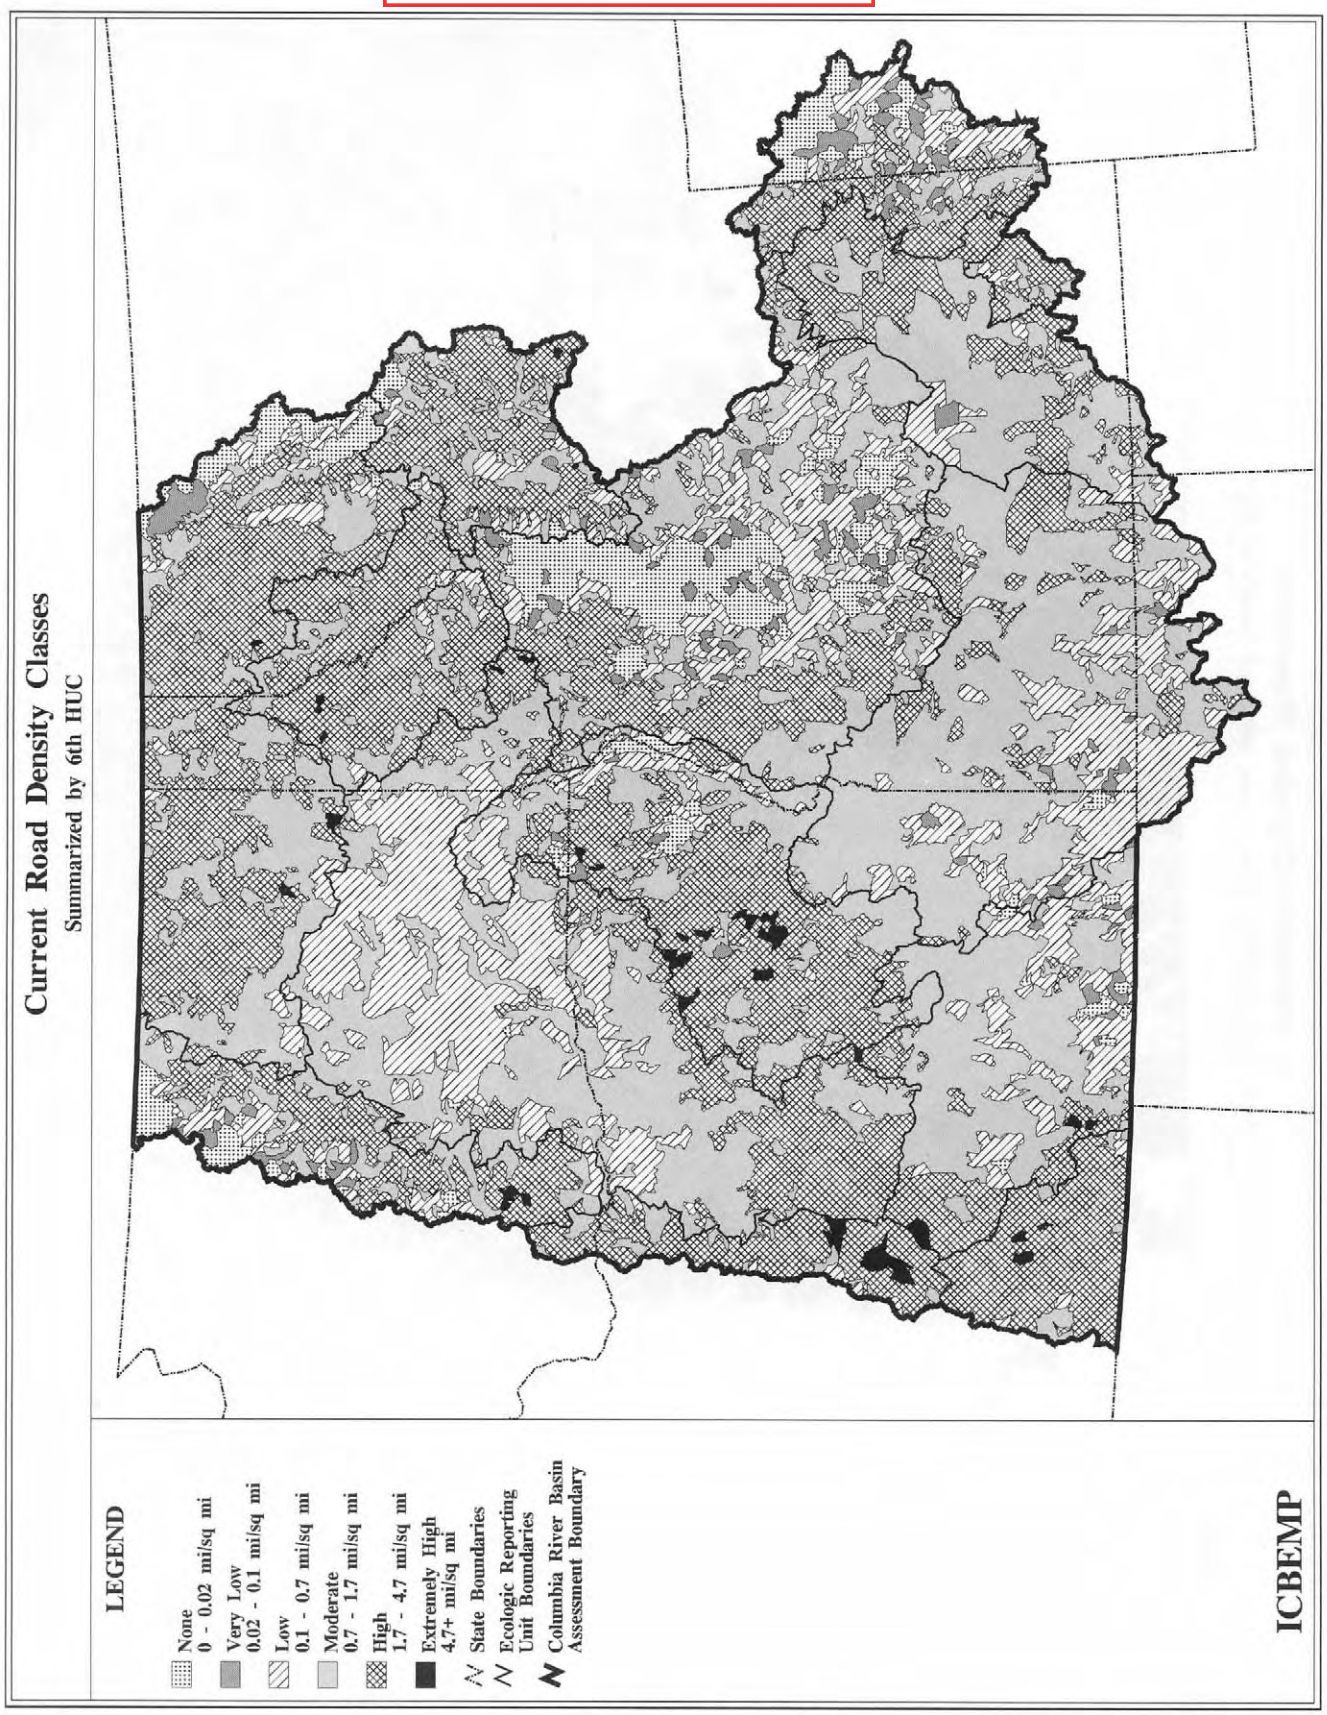
[1]NA = Not Applicable; no lands in this susceptibility category were detected at the broadscale.

[2]T = Trace amount < 0.05 percent.

Note: The percent of each ERU, when summed by susceptibility category, should total 100 percent for All land ownerships and should total 100 percent for BLM- and FS-administered lands.



Map 3.26—Susceptibility status of the Basin to invasion by cheatgrass, an exotic annual grass. Each shaded area (that is, susceptibility category) represents a grouping of cover types that were rated the same for susceptibility, and lie within the precipitation range (150-560 mm) of cheatgrass. Susceptibility ratings originate from the Susceptibility to Invasion Index.

Map 3.27—Susceptibility status of the Basin to invasion by yellow starthistle, an exotic annual forb. Each shaded area (that is, susceptibility category) represents a grouping of cover types that were rated the same for susceptibility, and lie within the precipitation range (300-635 mm) of yellow starthistle. Susceptibility ratings originate from the Susceptibility to Invasion Index.

Map 3.28—Current road density classes summarized by subwatershed (6th field hydrologic unit codes). Data used to formulate these classes was statistically extrapolated from sampled subwatershed road data. Because of the coarse scale of the data and the limited area that was sampled, this extrapolation is only applicable for broad-scale trends, subbasin summaries, or coarser analyses.

Map 3.29—Potentially degraded watersheds in the Basin. This map illustrates the relative hydrologic sensitivity of watersheds to acute, moderate, and high severity disturbance effects (such as roads, fire, harvest, and associated erosion and sediment transport potentials) combined with high and very-high road densities. High and very-high road densities were used as correlates of severity of disturbance. This map does not reflect susceptibility to soil disturbance due to the lack of vegetation cover or cumulative severe effects from chronic, low-severity disturbance (such as excessive livestock grazing pressure).

Map 3.30—Land ownership patterns within the Basin by subwatershed (6th field hydrologic unit codes).

Map 3.31—Wildfire occurrence/intensity risk on BLM- and Forest Service-administered lands. Wildfire occurrence is based on recent (1980s) wildfire ignitions. Risk of intense fire events is based on the potential for high amounts of contiguous fuels. The combined relative index indicates areas with combined risks of intense wildfire.

Map 3.32—High potential fuels, crown fire, and insect and disease mortalities. This map is limited to the dry forest PVG because of high relative risk of contiguous fuels, wildfire ignitions, severe fire-weather conditions, stressed environments, and fuel ladders that exacerbate crown fire potential in these environments.

Map 3.33—Rural population/wildland interface fire risk areas on Forest Service- and BLM-administered lands. This map is a combination of (1) the wildfire occurrence/intensity risk (map 3.30), and (2) current period estimates of areas in the urban and rural/wildland interface. The combination is therefore, the risk of wildfire damage to dwellings.

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes. Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes.
For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

Within the dry shrub PVG, exotic herblands were furthest outside the HRV, especially on BLM/FS lands (table 3.50). Several exotic plants were invasive into the dry shrub PVG within the Blue Mountains ERU, but cheatgrass, medusahead, and whitetop (*Cardaria draba*) were particularly extensive in land coverage. The upland herbland physiognomic type was substantially below the HRV on All ownerships, and especially within Other ownerships.

However, the historical area of the upland herbland physiognomic type on All ownerships may have been underestimated because of misclassification into the upland shrubland type. The areal extent of the upland shrubland type was generally higher than the HRV for All ownerships, primarily due to its extent in Other ownerships. The area of the upland shrubland on BLM/FS ownerships was at the upper end of the HRV. However, the historical area of the

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

upland shrubland physiognomic type on All ownerships may have been overestimated, due to misclassification of upland herbland into upland shrubland.

The physiognomic type composition of the cool shrub PVG is summarized in table 3.51. Exotic herblands were far outside the HRV, especially on BLM/FS lands. Of the weeds we considered, cheatgrass, medusahead, and whitetop probably had the most extensive coverage within the cool shrub PVG of the Blue Mountains ERU. The area of the upland herbland physiognomic type was substantially lower than the HRV, the area of the upland shrubland physiognomic type was on the high end of the HRV, and the area of the early-seral woodland physiognomic type was substantially above the HRV for All ownerships. The abundance of the early-seral woodland was primarily due to the encroachment of conifers as a result of fire exclusion. Similar trends were detected for BLM/FS and Other land ownerships, although more substantial changes occurred on Other ownerships.

The physiognomic type composition of the dry forest PVG in the Blue Mountains ERU is summarized in tables 3.52 and 3.53. The amount of exotic herbland was substantially underestimated because of aerial photo or satellite image obstructions by forest overstory cover. Cheatgrass and yellow starthistle were problematic exotic plants in the dry forest PVG of this ERU, especially within the fescue-bunchgrass, interior ponderosa pine, and shrub or herb/tree regeneration cover types. Areal extent of the upland herbland and upland shrubland physiognomic types were generally less than the HRV on All ownerships. The areal extent of the early-seral forest physiognomic type was generally at the upper range of HRV, whereas the areal extent of the mid-seral forest physiognomic type was nearly double the HRV.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

The late-seral single-layer forest type was almost nonexistent in the current period, whereas the late-seral multi-layer forest type was substantially above the HRV. These trends were similar for both BLM/FS and Other lands, although the late-seral multi-layer physiognomic type on Other lands was within the HRV. The cause of these trends was primarily due to the synergistic effect of fire exclusion and timber harvest practices.

Fire exclusion of lethal fires in the mid- and late-seral multi-layer physiognomic types resulted in an areal decline of the early-seral physiognomic type. Exclusion of fire permitted the succession of early-seral into mid-seral types. Fire exclusion also eliminated the non-lethal and mixed fires that maintained the late-seral single-layer physiognomic type, and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer physiognomic types. Timber harvest practices selectively removed the larger, shade-intolerant tree species that were more resistant to insects, disease, and stress mortality. Clearcutting and seed-tree timber-harvest activities commonly created small early-seral patches that contained no dead-standing trees, no scattered live trees, and high down fuel accumulations. This combination of factors, combined with a climatic trend (commencing in the 1980s) that seemed to produce drier spring, summer, and fall periods, resulted in changed conditions and higher risks of wildfire.

Current period dry forests, dominated by shade-tolerant tree species, were generally two to four times the HRV (table 3.53). Conversely, the late-seral shade-intolerant multi-layer forests on BLM/FS lands were below the HRV.

The composition of physiognomic types within the moist forest PVG varied among ownership strata in the Blue Mountains ERU (table 3.54). Although the areal extent of the early-seral physiognomic type in the current period occurred above the HRV for All ownerships, it was substantially above the HRV for BLM/FS ownerships, and substantially below the HRV for Other ownerships. This apparent contradiction was due to the lack of even-age harvest treatments (that is, clearcut or seed tree) and wildfire on Other lands, whereas these disturbances had been extensive on BLM/FS lands. The areal extent of the mid-seral forest type was within the HRV on All land ownerships, well below the HRV on BLM/FS lands, and well above the HRV on Other ownerships. Evidently, selective timber harvests on Other ownerships converted a substantial proportion of the late-seral single-layer forest type into the mid-seral forest type. The area of late-seral single-layer forest type occurred within the HRV on All and BLM/FS ownerships, whereas it occurred well below the HRV on Other ownerships. The late-seral multi-layer forest type occurred within the HRV for all ownership strata.

The moist forest PVG, dominated by shade-tolerant tree species in the mid-seral types, was well above the HRV on All ownerships, primarily due to selective harvests of large, shade-intolerant trees on Other lands (table 3.55). Shade-tolerant species were well above the HRV in late-seral multi- and single-layer physiognomic types on All ownerships, which was most likely the result of fire exclusion.

In response to the changes in regional and landscape conditions on forest and rangelands in the Blue Mountains ERU, the succession/disturbance regimes shifted substantially from maintenance regimes to long-cycle and retrogressive regimes (see table 3.6 for a description of succession/disturbance regimes). Consequently, the effects associated with wildfire, timber harvest, and grazing tended to be more severe in the current period. Without restoration of landscape structure and fuel conditions, the probability of returning to the succession/disturbance regimes that existed historically (that is, in the native system) was determined to be low.

Central Idaho Mountains ERU

The Central Idaho Mountains ERU has a high relief (300 to 3,700 m) complex of narrow valleys, breaks, and mountains (maps 3.3 and 3.17). Its topography is complex as a result of erosional processes and mountain glaciation. Landforms include a complex mix of foothills, breaks, mountains, and narrow valleys, with varied combinations of headwater and downstream subwatersheds (map 3.21). The ERU primarily occurs within ecoregion sections M332A, M332F, M332E, and M332G (map 3.1).

Precipitation averaged 68 centimeters per year within the Central Idaho Mountains ERU (range = 25 to 105 cm). The steep gradient in precipitation combined with the complex topography has resulted in very diverse vegetation in the Central Idaho Mountains ERU. Climate is strongly influenced by both oceanic storms from the west and the continental climates to the east. The rain-shadow effect of the Seven Devils Mountains to the west strongly affects this ERU. Precipitation primarily comes in the form of winter snows or spring rains. There is a moderately steep gradient from relatively moist spring conditions, to dry summer and fall conditions with a moderately long growing season. The moisture gradient results in vegetation and disturbance regimes that have high environmental diversity and dynamic biogeochemical energy relationships.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

Consequently, the Central Idaho Mountains ERU has moderately high rates of inherent NPP and nutrient cycling, with associated moderate carbon and water stresses in upland areas.

There have been substantial changes in the Central Idaho Mountains ERU fire regimes primarily as a result of fire exclusion (maps 3.22 and 3.23). Fire severity generally shifted from non-lethal or mixed to lethal, and non-lethal to mixed in the forest PVGs. This shift was caused by longer fire-return intervals. In the non-forest PVGs, fire severity generally shifted from mixed to lethal, and fire intervals increased due to fire exclusion, the removal of fine fuels by livestock grazing, and conifer encroachment.

From a regional-scale perspective, although the Central Idaho Mountains ERU has little area that receives less than 30 centimeters of annual precipitation (map 3.24), 15 percent of the years between 1895 and 1994 were drought years (table 3.38; climate division: Idaho Central Mountains). This level of drought frequency was nearly indistinguishable from other ERUs that are more dominated by arid, non-forest PVGs. Consequently, although the Central Idaho Mountains ERU received more precipitation in the fall-winter period compared with the ERUs dominated by arid, non-forest PVGs (45 cm; table 3.38), drought frequently affected both the forested and non-forested PVGs. At the landscape scale, the break landforms have a high component of areas that are steep with southerly exposures. These areas have high drought risks. Many of the steep breaklands are in nearly pristine condition at present because they are relatively inaccessible. Consequently, the steep breaklands may provide reference condition of native, or near-native, vegetation composition of grasslands and shrublands.

There has been a long history of livestock grazing of public lands along the outer perimeter of the Central Idaho Mountains ERU, but little livestock grazing has taken place in the central part of the ERU that became wilderness (map 3.25). Since the late-1800s, sheep and cattle have grazed on allotments on much of the public-ownership land. Improvements in range conditions and associated watershed conditions have occurred since the mid-1900s. However, the recovery process has been slowed to some degree because soils that are susceptible to erosion by wind are prevalent in this ERU (maps 3.18 and 3.34). In addition, slow recovery rates were evident in many of the high-elevation sheep allotments that lost soil cover and were subjected to extensive erosion. During the current period, many of these areas were dominated by early-seral forbs such as alpine knotweed (*Polygonum phytolaccifolium*), which provided very poor soil cover and had low productivity. Even though many of these allotments have been closed or have had their stocking rates substantially reduced, there are areas where soil cover or dominance by later-seral native species have not recovered. The non-forest and dry forest PVGs in the southwest and southeast portions of the Central Idaho Mountains ERU are particularly susceptible to invasion by exotic plants, particularly spotted knapweed and leafy spurge. In addition, the Selway-Bitterroot Wilderness in the northeast portion of this ERU currently has extensive infestations of spotted knapweed. In the current period, approximately 17 and 8 percent of the BLM/FS lands were of high susceptibility to invasion by spotted knapweed and leafy spurge, respectively. Similarly, approximately 22 and 14 percent of All lands in this ERU were of high susceptibility to invasion by spotted knapweed and leafy spurge, respectively (table 3.47; maps 3.35 and 3.36). Rangeland riparian areas, although commonly highly altered, have been recovering relatively quickly as a result of improved riparian management strategies.

In general, roads are virtually absent from the central portion of the ERU, but moderate to high road densities dominated the periphery of the ERU (map 3.28). Much of the Central Idaho Mountains ERU had sensitive watersheds because of the steep topography and highly-erosive granitic soils. Some of the sensitive subwatersheds on the outer edges of the ERU were affected by moderate to high road densities (map 3.29).

Map 3.34—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil salinity and soil erodibility to wind. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having these specific soil-property indicators: salinity of 8 to 16 millihmos per centimeter (mmhos/cm), and wind erodibility Groups 1 through 3; none of the other three, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Map 3.35—Susceptibility status of the Basin to invasion by spotted knapweed, an exotic biennial-perennial forb. Each shaded area (that is, susceptibility category) represents a grouping of cover types that were rated the same for susceptibility, and lie within the precipitation range (300-760 mm) of spotted knapweed. Susceptibility ratings originate from the Susceptibility to Invasion Index.

Map 3.36—Susceptibility status of the Basin to invasion by leafy spurge, an exotic perennial forb. Each shaded area (that is, susceptibility category) represents a grouping of cover types that were rated the same for susceptibility. Susceptibility ratings originate from the Susceptibility to Invasion Index.

The pattern of BLM/FS and Other land ownerships is relatively contiguous, occurring in large, unfragmented blocks in the Central Idaho Mountains ERU (map 3.30). Only the outer portions of the ERU have mixed BLM/FS and Other ownerships. Much of the BLM/FS lands have a moderate risk of fire occurrence and high-intensity wildfires, which would be difficult to suppress (map 3.31). Some of the area, particularly the break and narrow valley landforms, have high fire risks. Moderate and high fire risks have primarily been attributed to high wildfire occurrence from lightning ignition; dry summer and fall conditions; very complex and steep terrain; and a mosaic of woody and grass fuels that create the potential for severe fire behavior.

The outer periphery of the Central Idaho Mountains ERU is largely composed of dry forests that have high carbon and water stress, high fuel accumulations, and high potential for crown fires, forest insects, diseases, and stress-related mortalities (map 3.32). Historical timber-harvest practices often removed most of the large, shade-intolerant trees that are generally more resistant to these mortality agents. These large, shade-intolerant trees have largely been replaced by smaller, shade-tolerant tree species that are more susceptible to these types of mortality. We detected moderate fire risks within the rural/wildland interface on BLM/FS lands adjacent to other ownerships (map 3.33). Large wildfires or prescribed natural fires that have burned in the core of the ERU (which is mostly wilderness) have, on occasion, expanded out into the periphery of the ERU, particularly when late summer or early fall wind events occurred. If the fire fronts were sufficiently large, these fires became uncontainable. At the landscape scale, the high-risk areas often occur at the edge of the steep breakland environments. Rural developments are also typically associated with the bench or narrow valley landforms that lie on the edge of, or are interspersed within, the steep, complex topography of the break landforms. The break landforms typically occur on BLM/FS lands.

The PVG composition did not change substantially from the historical to the current period in the Central Idaho Mountains ERU (table 3.56, maps 3.11 and 3.12). Only 6 percent of the area was converted to agriculture, and a lesser amount to urban developments. Agricultural and urban development occurred primarily in the cool shrub, dry shrub, and dry grass PVGs. Across All current period ownerships, dry forest and cold forest PVGs dominated the ERU (27 and 25%, respectively), with lesser amounts of moist forest, cool shrub, dry shrub, and dry grass PVGs (16, 8, 8, and 7%, respectively). Approximately 1.5 percent of the ERU was converted into roads.

The PVG composition of BLM/FS lands was very similar to the composition of the ERU as a whole. For Other land ownerships, the current period composition was dominated by the agricultural and dry forest PVGs (6% and 5%, respectively).

The composition of physiognomic types within the dry grass PVG did not change substantially across ownership strata in the Central Idaho Mountains ERU (table 3.57). Not surprisingly, the areal extent of exotic herblands were far outside the HRV because this type was not present in the native system. However, the areal extent of exotic herbland was underestimated for the current period, especially on BLM/FS lands. The upland herbland physiognomic type was at the upper limit or above the HRV for all ownership strata. The woodland types did not occur across a substantial proportion of the dry grass PVG during the current period, although they were more common within the historical system (approximately 30%). However, the mid-scale assessment (Hessburg and others 1996a) did detect a measurable amount of conifer encroachment within the dry grass PVG in the Central Idaho Mountains ERU. These physiognomic types in the dry grass PVG normally occurred in relatively small patches, and consequently, were probably not detectable by broad-scale remote sensing.

In the dry shrub PVG of the Central Idaho Mountains ERU, the composition of physiognomic types did not vary across ownership strata.

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes. Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes.

For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

[3]+ = < 0.5%.

(table 3.58). The areal extent of exotic herblands was furthest outside the HRV because this type was not present in the native system. However, as with the dry grass PVG, the areal extent of exotic herblands on BLM/FS lands was underestimated for the current condition, and greatly underestimated on Other lands for the current period. The upland herbland physiognomic type was well below the HRV on BLM/FS lands and Other lands, most likely as a result of the invasion of exotic vegetation and the development of shrub types due to fire exclusion. Conversely, the upland shrubland physiognomic type was substantially above the HRV on BLM/FS lands and Other lands as a result of succession from the upland herbland type caused by fire exclusion.

The physiognomic type of the cool shrub PVG in the Central Idaho Mountains ERU is summarized in table 3.59. As expected, the areal extent of the exotic herbland physiognomic type was furthest outside the HRV, especially on BLM/FS lands.

[3] + = < 0.5%.

The area of the upland herbland type was well below the HRV, regardless of the ownership strata. The areal decline of upland herbland types was primarily a result of fire exclusion, which allowed the successional development into the upland shrubland type.

The ownership distribution of physiognomic types in the dry forest PVG is summarized in tables 3.60 and 3.61. The amount of exotic herbland was substantially underestimated because of forest overstory cover. The areal extent of the upland herbland and upland shrubland physiognomic types was generally below the HRV for the Central Idaho Mountains ERU as a whole. The amount of the early-seral and mid-seral forest types occurred toward the upper end or above the HRV. The late-seral single-layer forest type was well below the HRV, whereas the late-seral multi-layer forest type occurred at the upper limit of the HRV. The late-seral single-layer forest type largely converted into the mid-seral forest type because of insect, disease, and stress mortalities in the overstory layer, and growth of shade-tolerant layers in the understory. These trends were similar for BLM/FS and Other ownerships.

The aforementioned transitions occurred primarily as a result of fire exclusion. Fire exclusion substantially reduced the extent of the non-lethal and mixed fire regimes that maintained late-seral single-layer types, and that thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer types. Timber harvest activities largely occurred in the peripheral areas of the ERU, where the larger, shade-intolerant tree species were those primarily selected for harvest. These trees were more resistant to insect, disease, and stress mortality. Clearcutting and seed tree timber harvest activities commonly created small patches of early-seral structures containing few live or dead-standing trees, and high down fuel accumulations.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

Altered composition and structure, in conjunction with a climatic trend (commencing in the 1980s) that seemed to produce drier spring, summer, and fall periods, resulted in changed conditions and higher risks of wildfire.

The areal extent of the dry forest PVG dominated by shade-tolerant tree species was generally at the upper limit of the HRV. The conversion to dominance by shade-tolerant species was not as dramatic in the Central Idaho Mountains ERU as compared with the Blue Mountains ERU, because there had been less selective harvest of the large shade-intolerant trees in the Central Idaho Mountains ERU.

The composition of physiognomic types within the moist forest PVG is summarized in tables 3.62 and 3.63. The areal extent of the early-seral forest type was within the HRV for the Central Idaho Mountains ERU as a whole and BLM/FS ownerships within the ERU. However, it was below the HRV on Other ownerships. The area of mid-seral forest type was at the high end of the HRV in the ERU as a whole and in BLM/FS ownerships, whereas it was well above the HRV on Other ownerships. The late-seral single-layer forest physiognomic type was below the HRV for all ownership strata, whereas the late-seral multi-layer forest physiognomic type occurred at the low end of the HRV for BLM/FS and Other ownerships. Physiognomic types dominated by shade-tolerant tree species were generally at the upper limit of, or slightly above the HRV.

The physiognomic type composition of the cold forest PVG in the Central Idaho Mountains ERU is summarized in tables 3.64 and 3.65. The areal extent of the early-seral physiognomic type was substantially higher than the HRV for the ERU as a whole, as well as for BLM/FS ownerships. On Other ownerships, the area of the early-seral physiognomic type occurred within the HRV. The mid-seral forest physiognomic type was below its HRV for all ownership strata. The areal extent of the late-seral multi-layer forest types occurred within their HRV for all ownership strata, whereas the areal extent of the late-seral single-layer forest types occurred below the HRV for Other ownerships and above the HRV for BLM/FS and All ownerships. A general shift from mid- and late-seral to early-seral types appeared to be related primarily to the mortality of whitebark pine caused by blister rust. In addition, there was a lack of successful regeneration of whitebark pine and subalpine larch (*Larix lyallii*) in many areas as a result of fire exclusion. Whitebark pine and subalpine larch both require fire for seedbed preparation.

Physiognomic types within the cold forest PVG, dominated by shade-tolerant and shade-intolerant species, is summarized in table 3.65. The amount of the early-seral shade-tolerant forest type was substantially above the HRV for All ownerships and BLM/FS lands, whereas in Other ownerships it occurred at the lower end of the HRV. The areal extent of late-seral and mid-seral shade-intolerant forest types were well below HRV, which supported our interpretation that shade-intolerant whitebark pine had declined due to fire exclusion and mortality from blister rust, and was being replaced by shade-tolerant subalpine fir. The areal extent of shade-intolerant subalpine larch also declined as a result of fire exclusion, and had been replaced by subalpine fir.

In response to the changes in regional and landscape conditions on forest and rangelands, the primary change in succession/disturbance regimes appeared to be a shift from moderate and accelerated cycles to long and retrogressive cycles. Most of the areas within the wilderness and roadless areas had low probability for re-establishment of these regimes given the limitations of prescribed fire and the effects of blister rust on whitebark pine. The existing prescribed natural-fire program has had a limited number of ignitions, as well as a limited number of fires that have been allowed to burn as prescribed natural fires. The small number of ignitions were

the result of efficient fire-suppression efforts. Existing wilderness and roadless areas have a high probability for restoration of historical regimes provided that implementation of a prescribed fire program has an adequate number of ignitions.

The roaded areas on the periphery of the Central Idaho Mountains ERU generally had the highest departures from the HRV regimes. There was a low probability of returning these roaded systems to the native succession/disturbance regimes without restoration of landscape structure, fuel conditions, whitebark pine, and fire.

Columbia Plateau ERU

The Columbia Plateau ERU is located primarily in Washington and Oregon, with a portion extending into northern Idaho (map 3.3). This ERU has a low relief (20 to 2,300 m) complex of wide valleys and plains with interspersed breaks, foothills, and mountains. Topography is generally gentle as a result of relatively level volcanic flows and wind-blown deposition (map 3.17). The interspersed breaklands developed from major floods during geologic glacial recessions and subsequent erosional processes. Landforms include a mix of valleys, plains, foothills, and breaks.

[3] + = < 0.5%.

Most watersheds are oriented around mainstem streams; most headwater watersheds are located in adjacent ERUs (map 3.21). The Columbia Plateau ERU primarily falls within ecoregion sections 342I, 342G, and 342H (map 3.1).

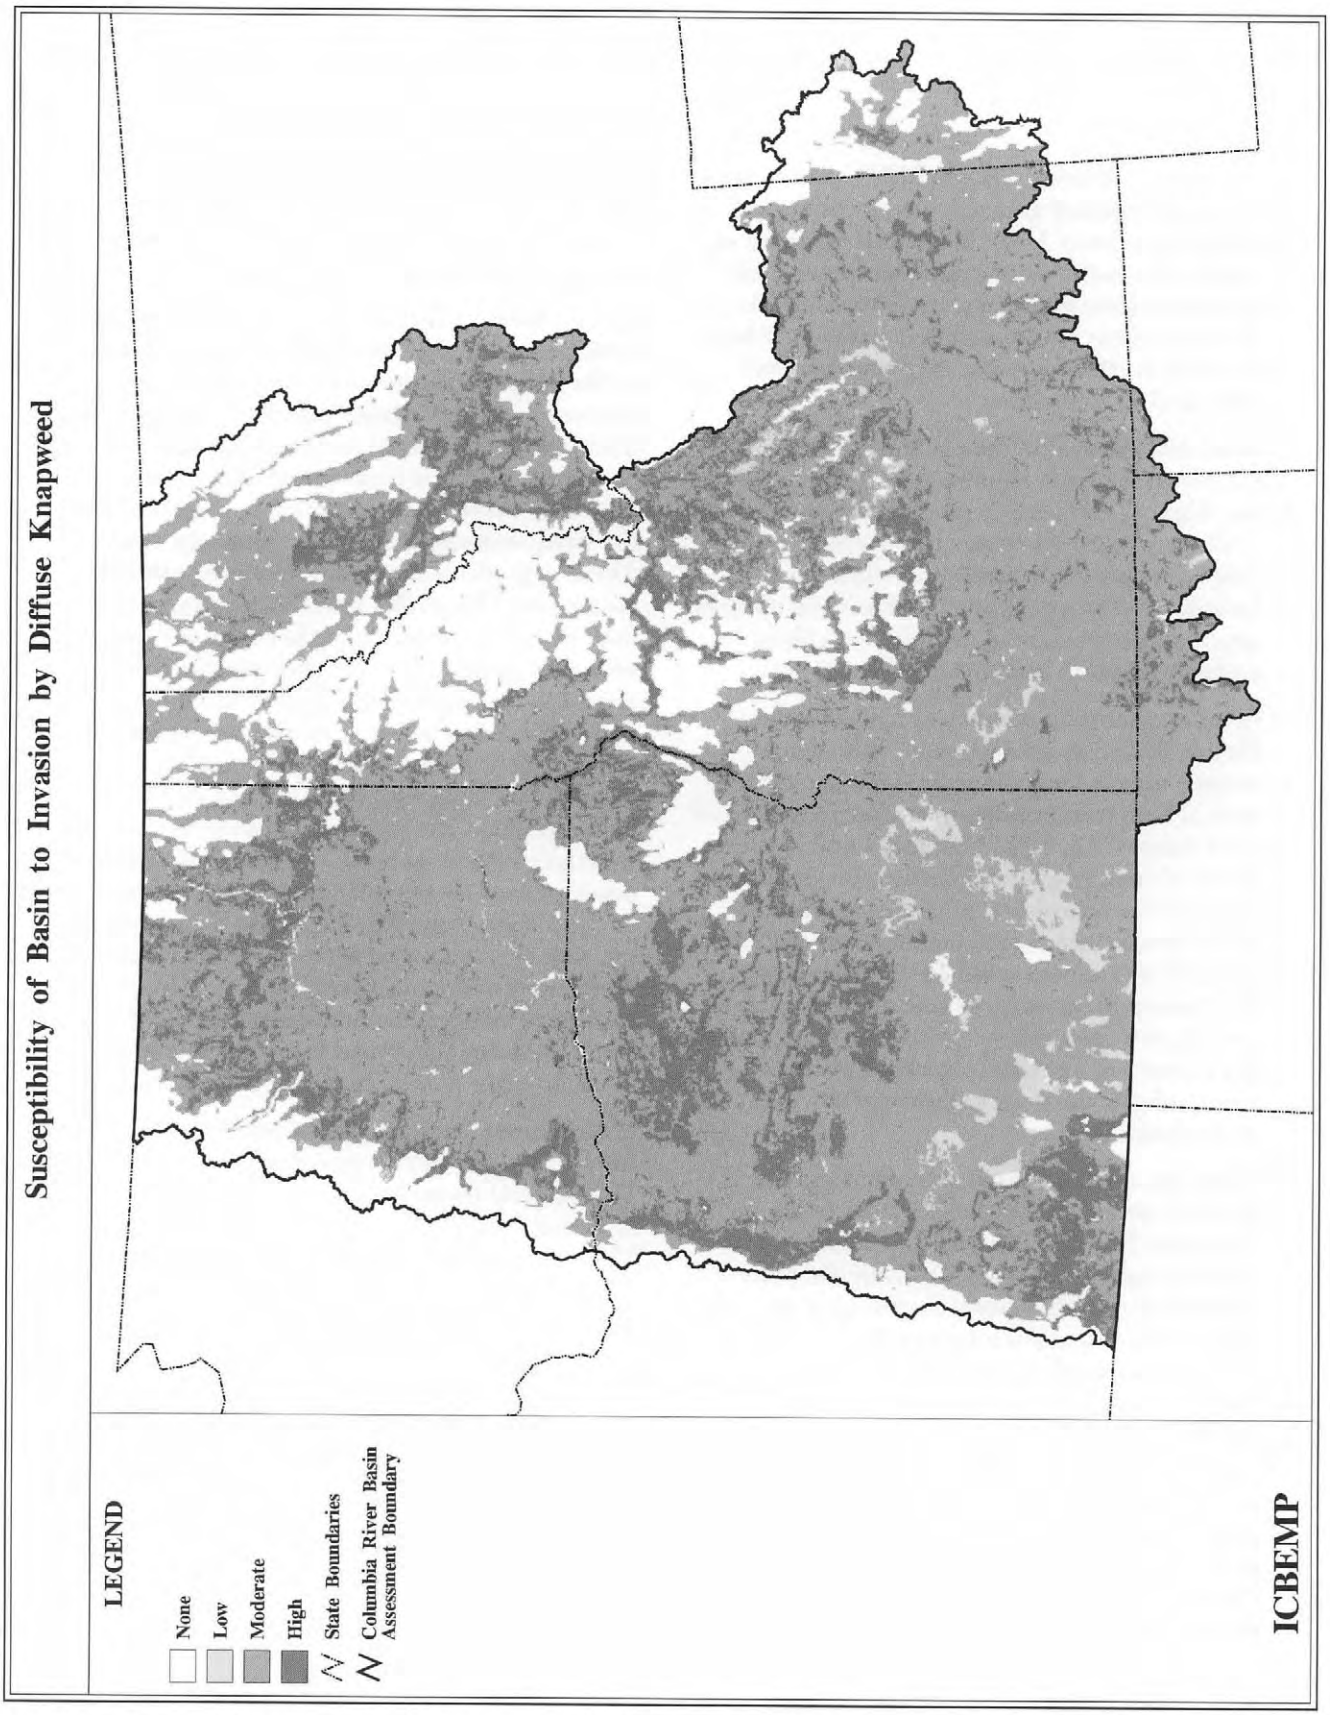
Precipitation averages 36 centimeters per year (range = 22 to 102 cm). However, most of the Columbia Plateau ERU has a fairly low variation of precipitation. The lower and higher precipitation areas are confined to river breaklands and scattered mountains, respectively. Climate is strongly influenced by oceanic storm patterns and the rain-shadow effect of the Cascade Mountains to the west. Precipitation primarily comes in the form of rain or snow in the fall and winter, with some rain in the spring. Frequent winds and relatively high temperatures during the growing season cause high rates of evapotranspiration and soil surface moisture desiccation. There is a moderately steep gradient from moist fall, winter, and spring conditions to very dry summer and early fall conditions. The growing season is relatively long compared with other ERUs. As a result, the Columbia Plateau ERU has relatively low diversity of vegetation and disturbance regimes. However, because of the long growing season and high soil productivity, biogeochemical energy relationships are very dynamic. Consequently, the inherent rates of NPP and nutrient cycling are high, and the associated carbon and water stresses on upland sites are moderate.

Agricultural development and fire exclusion substantially changed the fire regimes of the Columbia Plateau ERU (maps 3.22 and 3.23). Agricultural development also substantially reduced the fire frequency in the grasslands, shrublands, and forests. Fire severity in the forest PVGs generally shifted from non-lethal and mixed to lethal, and from non-lethal to mixed. In the non-forest PVGs, fire severity shifted from non-lethal and mixed to lethal, and fire-return intervals decreased as a result of the invasion of flammable annual grasses.

A substantial proportion of the Columbia Plateau ERU receives less than 30 centimeters of annual precipitation (map 3.24). Drought was documented for 16 to 18 percent of the years between 1895 and 1994 (table 3.38; climate divisions: Washington Palouse-Blue Mountains, Washington Central Basin, Oregon North Central, and Oregon South Central). Conversely, relatively wet periods were documented only 4 to 7 times during that same timeframe (table 3.38). The combination of (1) inherently meager annual precipitation, (2) relatively frequent drought years, and (3) relatively infrequent periods believed to be favorable for perennial plant recruitment, has reduced the potential for non-forest PVG restoration on sites that experienced exotic plant invasions or were subject to excessive livestock grazing pressure.

The Columbia Plateau ERU has a high component of break landforms that are steep and have southerly exposures. Most of these breaklands are relatively accessible and have been invaded by exotic forbs or annual grasses. Most upland rangeland types on private lands have also been invaded by exotic forbs or annual grasses. BLM/FS lands that compose only 11 percent of the Columbia Plateau ERU, exist primarily as small parcels surrounded by agricultural land. BLM/FS lands have also been extensively invaded by exotic forb or annual grasses. Examples of exotic plants that have been problematic in this ERU are cheatgrass, yellow starthistle, diffuse knapweed, and medusahead. During the current period, approximately 45, 20, and 2 percent of the BLM/FS lands in the Columbia Plateau ERU were of high susceptibility to invasion by cheatgrass, diffuse knapweed (*Centaurea diffusa*), and yellow starthistle, respectively. Approximately 34, 13, and 27 percent of All lands in this ERU were deemed of high susceptibility to invasion by cheatgrass, diffuse knapweed, and yellow starthistle, respectively (table 3.47; maps 3.26, 3.27 and 3.37). In addition, soils that shrink or swell from drying or wetting were extensive in the southern portion of this ERU (maps 3.19 and 3.20) and thus, were susceptible to medusahead establishment.

The entire Columbia Plateau ERU has had a long history of livestock grazing on both private and public lands (map 3.25). Some improvements in rangeland conditions and associated watershed conditions have occurred since the mid-1900s. However, many stream and river banks have been downcut to the extent that they have lost their associated riparian areas.



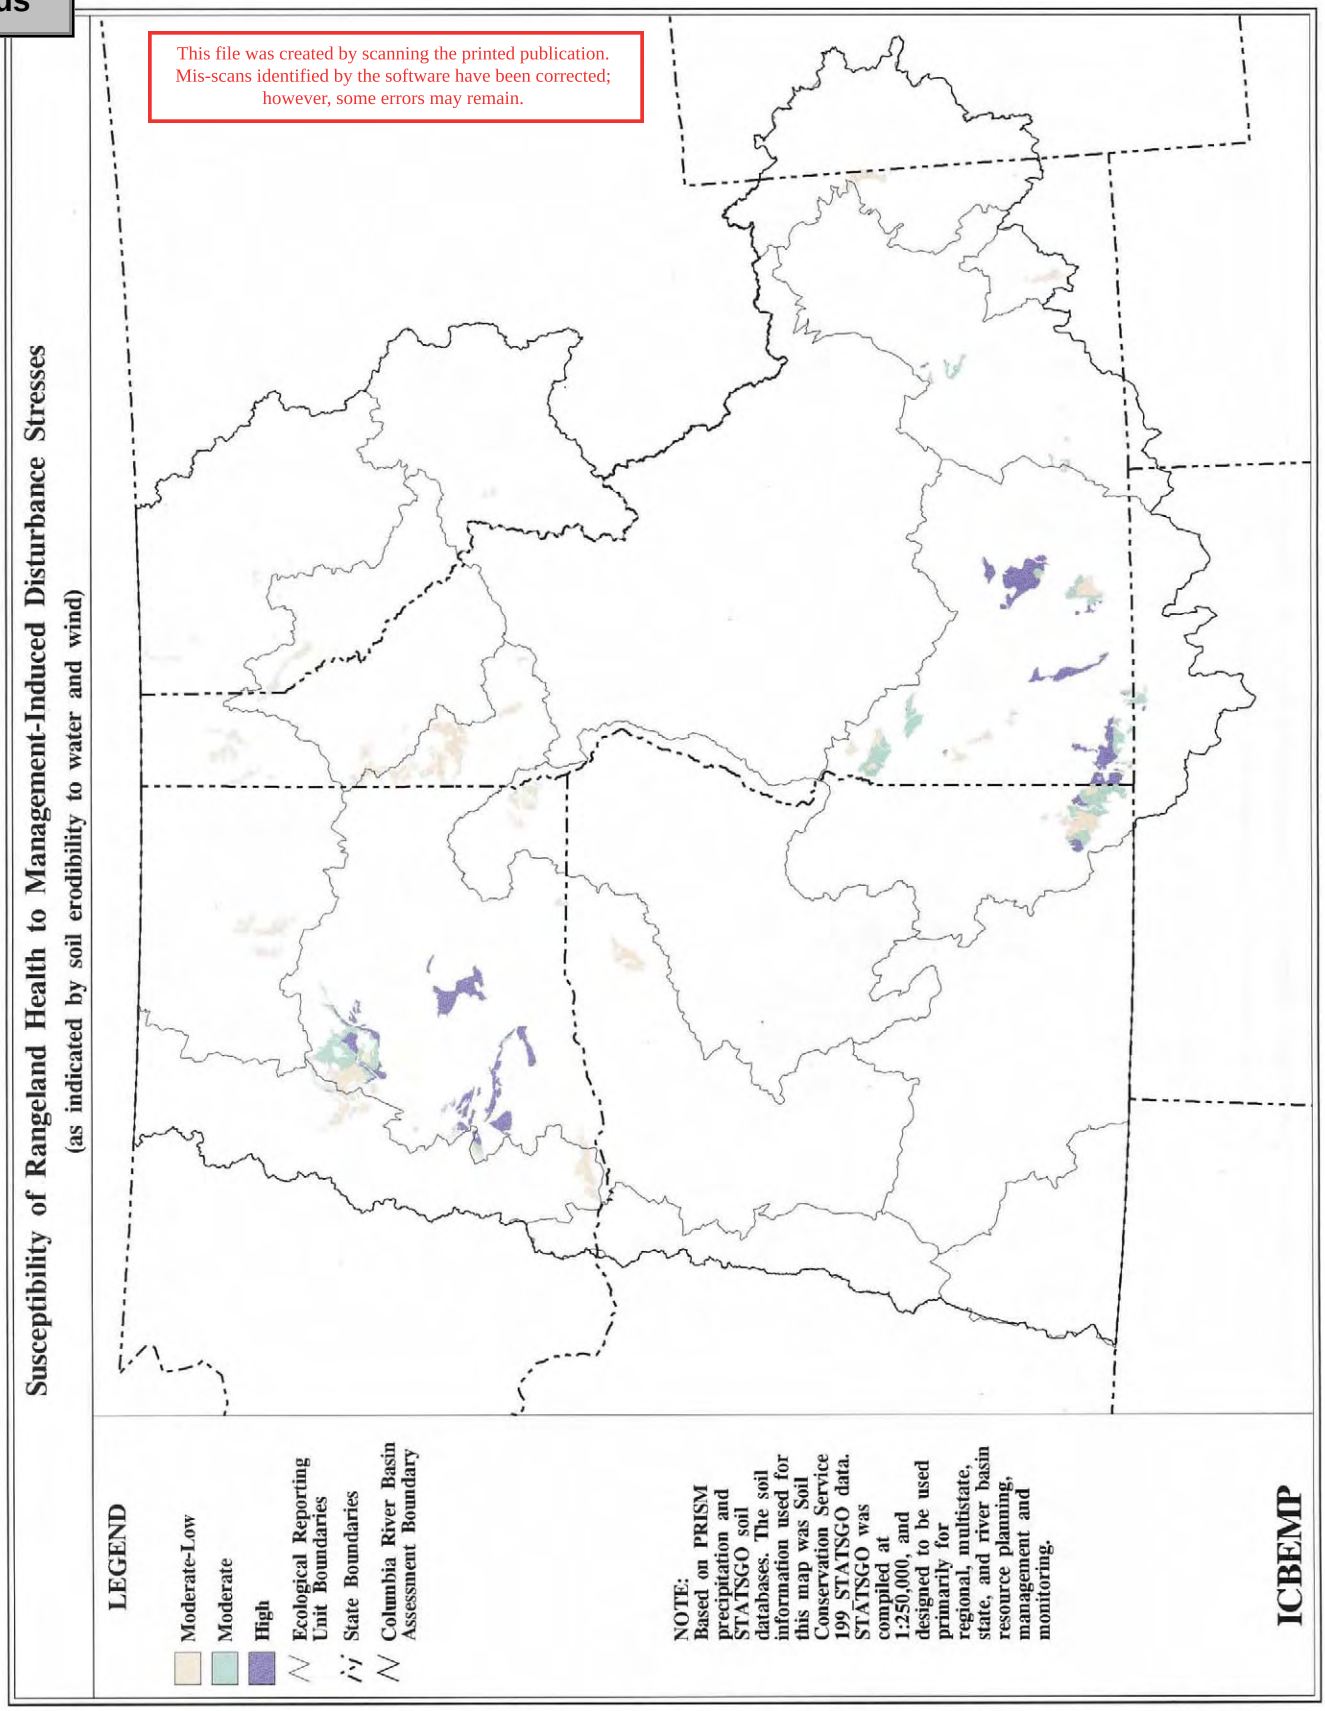
Road densities within the Columbia Plateau ERU are primarily low to moderate; few areas have very low, high, or extremely high densities, or no roads at all (map 3.28). However, because there were only a few mid-scale subbasins sampled, and because there was difficulty in identifying roads in agricultural terrain, road densities were likely underestimated (Menakis and others 1996).

In the current period, much of the Columbia Plateau ERU contained sensitive watersheds because soils lacking adequate vegetation cover were of high susceptibility to erosion by water and wind (maps 3.18, 3.38, 3.39 and 3.40). However, many of these areas were in private ownership and managed for agricultural purposes, and are thus, not evident in map 3.29. Lands in public ownership generally had adequate soil cover that minimized their susceptibility to erosion (map 3.29). Consequently, due to extensive agricultural development, the erosion risks of the Columbia Plateau ERU were probably the most extensive of any ERU in the Basin.

There are minor amounts of highly-fragmented BLM/FS and Other land ownerships in the Columbia Plateau ERU (mostly classified as "uniform other" in map 3.30). Only the outer portions of the ERU contain substantial areas of BLM/FS lands, which are generally in the mixed or mosaic ownership classes. A minor portion of the BLM/FS lands has moderate risk of fire occurrence and associated high-intensity wildfires that would be difficult to suppress (map 3.32). High-intensity wildfires have generally occurred in the peripheral areas of the ERU. At the landscape scale, there are some areas, particularly the break landforms, that have high fire risk. The moderate and high risks were related primarily to potential wildfire occurrence from human-caused ignition; dry spring, summer, and fall conditions; complex break terrain; and flammable annual-grass fuels that created the potential for severe fire behavior.

The Columbia Plateau ERU has few areas in the outer periphery that have high fuel accumulations or the potential for crown fires, forest insects, diseases, and stress-related mortalities (map 3.32). These mortality agents have been associated with dry forests that have high carbon and water stress. Historical harvest practices often removed most of the large, stress-resistant, shade-intolerant trees. These large, shade-intolerant trees have generally been replaced by smaller, shade-tolerant tree species that are more susceptible to the above-mentioned mortality agents. There are moderate fire risks related to the rural/wildland interface on the BLM/FS lands adjacent to rural development (map 3.33). However, BLM/FS ownership is minor in the Columbia Plateau ERU. At the landscape scale, the high-risk areas often occur at the edge of the steep break environments. Rural developments are typically associated with the adjacent valley and plain landforms that are on the edge or interspersed with the steep, complex topography of the break landforms. The break landforms predominantly occur on the BLM/FS lands, although substantial break landforms also occur on other public lands.

PVG composition changed substantially from the historical to the current period in the Columbia Plateau ERU (maps 3.11 and 3.12). We compared historical PVG composition to current period PVG composition by land ownership strata (table 3.66). Except for the development of roads, there was no substantial change on BLM/FS lands. On Other ownerships, 48 percent of the area was converted to agriculture, most of which came from the dry grass and dry shrub PVGs. Across All ownerships, dry grass, dry shrub, cool shrub, dry forest, and agricultural PVGs dominated the ERU, with a lesser amount of the moist forest PVG. Approximately 1.7 percent of the total area was roaded.



Map 3.37—Susceptibility status of the Basin to invasion by diffuse knapweed, an exotic annual or occasional perennial forb. Each shaded area (that is, susceptibility category) represents a grouping of cover types that were rated the same for susceptibility, and lie within the precipitation range (150-890 mm) of diffuse knapweed. Susceptibility ratings originate from the Susceptibility to Invasion Index.

Map 3.38—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil erodibility to water and wind. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having these specific soil-property indicators: a soil erodibility factor (K factor) exceeding 0.37, and wind erodibility Groups 1 through 3; none of the other three, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Map 3.39—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil erodibility to water. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having an erodibility factor (K factor) exceeding 0.37; none of the other four, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Map 3.40—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil erodibility to water and wind, and salinity. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having these specific soil-property indicators: a soil erodibility factor (K factor) exceeding 0.37, and salinity of 8 to 16 millihmos per centimeter (mmhos/cm), and wind erodibility Groups 1 through 3; neither of the other two, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes. Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes.

For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

BLM/FS land ownerships in the Columbia Plateau ERU were fairly evenly distributed between the dry forest, moist forest, dry shrub, and cool shrub PVGs. In the current period, BLM/FS roads accounted for 0.4 percent of the land cover. For Other ownerships, the current composition was dominated by the agricultural, dry shrub, dry forest, cool shrub, and dry grass PVGs. Roads on Other ownerships accounted for 1.3 percent of the land area.

None of the PVGs met the 5 percent BLM/FS land ownership criteria for the Columbia Plateau ERU. However, we described PVG types and succession/disturbance regimes for the dry grass, dry shrub, cool shrub, and dry forest PVGs because of their importance from a coarse-filter biodiversity perspective. The BLM/FS lands were generally the only remaining areas that were not converted to agriculture, dominated by exotic plants, or at high risk of future conversion. Consequently, these lands could play an important role in conserving some semblance of the native biota in the Columbia Plateau ERU.

The physiognomic type composition of the dry grass PVG of the Columbia Plateau ERU is summarized in table 3.67. The areal extent of the exotic herbland type was furthest outside the HRV, primarily on BLM/FS lands. However, the amount of exotic herbland type on Other and BLM/FS lands was substantially underestimated for the current period condition, by possibly as much as 50 percent in the upland herbland physiognomic type. Exotic plants that are especially problematic within the current period dry grass PVG included yellow starthistle, cheatgrass, and dalmatian toadflax (*Linaria dalmatica*). For the dry grass PVG that was not converted to agriculture, the upland herbland physiognomic type declined from the HRV for all ownerships. The mid-seral woodland physiognomic type increased substantially. This combined shift was a result of exotic plant invasions, fire exclusion in woodlands, and fire regime changes in the exotic herbland type. On All ownerships, the historical system was generally dominated by upland herbland and was maintained by frequent non-lethal fires. Composition and relationships on BLM/FS and Other ownerships generally followed the same pattern as on All ownerships.

The physiognomic type composition for the dry shrub PVG is summarized in table 3.68. The extent of exotic herblands on BLM/FS, Other, and All ownerships was substantially underestimated. For the dry shrub PVG that was not converted to agriculture, the areal extent of the upland herbland physiognomic type was extremely low and the upland shrubland physiognomic type was high compared to the HRV for BLM/FS, Other, and All land ownerships. This combined shift was a result of fire exclusion.

The exotic plants that are especially problematic in this PVG include cheatgrass, medusahead, and diffuse knapweed. Because the dry shrub PVG had such extensive exotic vegetation coverage, a return of native fire regimes would likely cause an expansion of communities dominated by exotics.

The composition of physiognomic types within the cool shrub PVG is summarized in table 3.69. For the cool shrub PVG that was not converted to agriculture, the areal extent of the upland herbland and upland shrubland physiognomic types was quite low, and the early- and mid-seral woodland physiognomic types were high compared to the HRV for All ownerships. These trends were a result of fire exclusion. The amount of the exotic herbland type was substantially underestimated, which means that the amount of the upland herbland and upland shrubland types could have been much less than our predictions indicated. The return of native fire regimes to the cool shrub PVG would likely promote the expansion of communities dominated by exotic vegetation, and further the subsequent decline of the upland herbland and upland shrubland types. The trends for BLM/FS and Other land ownerships followed similar patterns as those on All ownerships.

Tables 3.70 and 3.71 display the physiognomic type composition by ownership strata for the dry forest PVG. The amount of the exotic herbland physiognomic type was substantially underestimated because of forest overstory cover. The abundance of the early-seral forest type was generally at the lower end of the range of the HRV for All ownerships. The areal extent of the mid-seral forest type was twice

[3]+ = < 0.5%.

as high as the HRV maximum. The areal extent of the late-seral multi-layer forest type was at the high end of the range, whereas the late-seral single-layer forest type was essentially non-existent compared with a very-high HRV level. There were similar trends for BLM/FS and Other ownerships. These conditions related primarily to the exclusion of non-lethal and mixed-underburning fires, and the harvesting of large, shade-intolerant trees. The late-seral single-layer forest types shifted to mid-seral types as a result of selective harvest practices, insects, disease, and stress mortality in the overstory layer, as well as the subsequent growth of shade-tolerant layers in the understory. Fire exclusion eliminated the non-lethal and mixed fires that maintained the late-seral single- and multi-layer types, and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer types.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

Clearcut, seed tree, shelterwood, and group selection timber-harvest activities commonly created a mosaic of small patches of the early-seral types with no dead-standing trees, no scattered small live trees, and high down-fuel accumulations. In the matrix areas surrounding these early-seral patches, the large trees and dead-standing trees were often selectively harvested. These practices resulted in an overall landscape forest pattern with high-risk conditions for fire, insect, disease, and stress mortality. When shade tolerance was included as a descriptor of the physiognomic type (table 3.71), it was apparent that the mid- and late-seral forests dominated by shade-tolerant tree species were substantially above or at the upper limit of the HRV.

In response to the changes in regional and landscape conditions on forest and rangelands, the succession/disturbance regimes went through a substantial shift from moderate-cycle and maintenance regimes to short-cycle and retrogressive-cycle regimes. Much of the area is roaded and succession/disturbance regimes changed due to timber harvest and fire exclusion. There was a low probability of returning the succession/disturbance regimes to their historical compositions without the restoration of perennial vegetation and landscape structures.

Lower Clark Fork ERU

The Lower Clark Fork ERU is located primarily in Idaho and Montana (map 3.3). This ERU has a high relief (300 to 2,500 m) complex of narrow valleys and steep mountains (map 3.17). Topography is generally steep and complex. Interspersed break areas are quite complex as a result of major floods during geologic glacial recessions and their subsequent erosional processes.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

Landforms include a mix of mountains, foothills, and breaks with narrow valleys. Downstream and upstream watersheds are juxtaposed (map 3.21).

Precipitation for the Lower Clark Fork ERU averages 110 centimeters per year (range 63 to 141 cm). The Lower Clark Fork ERU is primarily in ecoregion section M333D (map 3.1).

Climate is strongly influenced by the oceanic storm patterns from the west. The Clark Fork River and the ERU itself act as a funnel for westward-moving storms. Although the mountains in this ERU are relatively high and run from north to south, they do not function as a substantial barrier to storms because of the deep cut of the Clark Fork River valley and the position of several relatively low, wide mountain passes. In addition, the foothills and mountains on the western side of the ERU provide a gradual uplift that generally does not produce a sharp rain-shadow effect, but instead a relatively uniform increase in precipitation throughout the ERU. Precipitation occurs primarily in the form of winter snows, spring rains, and summer thunder storms and showers. There is a moderately steep gradient from moist winter and spring conditions, to dry summer and fall conditions, with a moderately long growing season.

Soils in the Lower Clark Fork ERU are fairly productive as a result of volcanic ash deposition. The climate and productive soils have resulted in moderately high inherent NPP and nutrient cycling. The ERU has very dynamic disturbance regimes because of this inherent productivity combined with steep and complex topography, and associated moderate carbon and water stress on upland areas.

There were substantial changes in fire regimes from the historical to the current period in this ERU, primarily as a result of timber harvest activities combined with fire exclusion (map 3.22 and 3.23). In general, longer fire intervals caused the fire severity in the forest PVGs to shift from a mixture of classes (that is, non-lethal, mixed, and lethal) in the historical period to lethal in the current period.

From a regional perspective, the Lower Clark Fork ERU is not in a high-risk, drought climate. The ERU averaged greater than 30 centimeters annual precipitation (map 3.24). At the landscape scale, a few areas that have steep topographic settings and southerly exposures have high drought-risk environments. In the current period, these areas were typically dominated by the dry grass PVG and susceptible to exotic forb invasions, particularly spotted knapweed and sulfur cinquefoil (*Potentilla recta*). The upland herbland physiognomic type within the dry forest and moist forest PVGs was also particularly susceptible to invasion by spotted knapweed and sulfur cinquefoil. Approximately 10 percent of the entire Lower Clark Fork ERU and 3 percent of BLM/FS lands in this ERU were of high susceptibility to invasion by spotted knapweed (table 3.47; map 3.35). A relatively small portion of this ERU had a history of livestock grazing on public lands (map 3.25).

Road densities in the Lower Clark Fork ERU are generally high with lesser amounts of other categories (map 3.28). High road densities typically occur in subwatersheds that are sensitive to the disruption of hydrologic regimes (map 3.29). Relative to subwatersheds dominated by rangelands, forested subwatersheds are generally steeper, have less developed soils, and are more susceptible to erosion and sediment transport via road networks. Forested subwatersheds developed for timber harvest, typically have high road densities. As previously discussed, in contrast to hard-surface roads, roads in forested subwatersheds are commonly surfaced with gravel or native materials that are susceptible to sediment transport. Because of the narrow draws and valley bottoms of the Lower Clark Fork ERU, many roads were historically developed in close proximity to the stream network. Consequently, these roads often constrict the stream floodplain energy and have very short distances for sediment delivery.

The ownership pattern of BLM/FS and Other land is moderately fragmented in the Lower Clark Fork ERU (map 3.30). There are large areas with relatively uniform BLM/FS land ownership and

many interspersed areas with mixed and mosaic ownership patterns. A large portion of the BLM/FS lands have a moderate risk of fire occurrence and associated high-intensity wildfires that could be difficult to suppress (map 3.31). These areas generally occur on the lower elevations and steeper terrain of the dry forest PVG. At the landscape scale, there are areas, particularly the break landforms, that have high risks of fire. Moderate and high fire risks have been related to potential wildfire occurrence from lightning and human-caused ignition; dry spring, summer, and fall conditions; complex steep terrain; and high forest fuel-loadings that create the potential for severe fire behavior.

The Lower Clark Fork ERU has areas located around the outer periphery with high fuel accumulations, potential for crown fire, and forest insect-, disease-, and stress-related mortalities (map 3.32). These areas have been associated with dry forest and moist forest PVGs that have high carbon and water stress. Historical harvest practices in forest PVGs often removed most of the large, shade-intolerant trees that were generally resistant to the above-mentioned mortality agents. The large, shade-intolerant trees have generally been replaced by smaller, more susceptible, shade-tolerant tree species.

There are moderate fire risks associated with the rural/wildland interface on BLM/FS lands (map 3.33). At the landscape scale, the high-risk areas often occur at the edge of the steep foothill or mountain environments. Rural developments are typically associated with the adjacent narrow valley landforms that are on the edge of, or interspersed with, the steep foothill or mountain landforms.

With the exception of road development, PVG composition did not change substantially between the historical and current periods in the Lower Clark Fork ERU, (table 3.72; maps 3.11 and 3.12). The moist forest and dry forest PVGs dominated the ERU, regardless of ownership strata. Approximately 3.4 percent of the total area was in roads, of which BLM/FS contributed 2.2 percent and Other ownerships contributed 1.1 percent.

We summarize the composition of physiognomic types within the dry forest PVG in the Lower Clark Fork ERU (tables 3.73 and 3.74). The areal extent of the early-seral forest physiognomic type was at the lower end or below the range of the HRV for All land ownerships. The area of the mid-seral forest type was almost two to three times as high as the HRV maximum. The area of the late-seral multi-layer forest physiognomic type was very low and the late-seral single-layer forest type was non-existent in comparison to the HRV. Similar trends were found for BLM/FS and Other land ownerships.

The above trends resulted from the harvest of late-seral forests and fire exclusion. The late-seral single- and multi-layer forests physiognomic types shifted to mid-seral forest types because of harvest activities, and insect, disease, and stress mortalities in the overstory layer. When forests were harvested using clearcut and seed tree treatments and then planted, succession processes were accelerated. Consequently, mid-seral structures developed faster than was typical in native systems. Fire exclusion eliminated non-lethal and mixed fires that maintained late-seral single- and multi-layer physiognomic types, and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer types. The shade-tolerant trees were susceptible to insects, disease, and stress mortality. Clearcut, seed tree, shelterwood, and group-selection timber-harvest activities commonly created a mosaic of small early-seral patches with no dead-standing trees, no scattered small live trees, and high down-fuel accumulations. In the matrix areas surrounding the patches, the large trees and dead-standing trees were often selectively harvested. This combination of activities commonly resulted in an overall landscape forest pattern with high risk conditions for fire, insect, disease, and stress mortality.

The areal extent of the mid-seral forest physiognomic types, dominated by shade-tolerant tree species, was five times the upper limit of the HRV on All ownerships. This system was at very high risk of substantial mortality to insects, disease, and stress, as well as large, high-intensity fires.

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes. Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

The physiognomic type composition is summarized for the moist forest PVG in the Lower Clark Fork ERU in tables 3.75 and 3.76. The area of the early-seral forest physiognomic type was generally at the lower end of the range of the HRV for All land ownerships. The extent of the mid-seral forest physiognomic type was almost twice as high as the HRV maximum. The abundance of the late-seral multi- and single-layer forest types was very low in comparison to the HRV. There was a similar trend for BLM/FS and Other land ownerships. These trends were a result of the harvest of late-seral forests and exclusion of fire. The late-seral single- and multi-layer forest types shifted to mid-seral because of harvest practices and insect, disease, and stress mortalities in the overstory layer. In areas where the forests were harvested using clearcut and seed tree treatments, forest succession was accelerated toward mid-seral types, at a rate faster than the HRV, through the use of advanced regeneration plantings. Fire exclusion eliminated the non-lethal and mixed fires that maintained late-seral single- and multi-layer types, and

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer types. Clearcut, seed tree, shelterwood, and group-selection timber-harvest activities commonly created a mosaic of small early-seral patches with no dead-standing trees, no small live trees, and high down-fuel accumulations. In the matrix areas surrounding these patches, the large trees and dead-standing trees were generally harvested. This combination of factors resulted in an overall landscape forest pattern with high-risk conditions for fire, insects, disease, and stress mortality.

The areal extent of the mid-seral forest physiognomic types, dominated by shade-tolerant tree species, was three times the upper limit of the HRV (table 3.76). The amount of the shade-intolerant mid-seral forest type was at the upper limit of the HRV. The loss of western white pine from this system due to blister rust infestations resulted in the lack of a fast-growing dominant tree for moist environments. The moist forest system in the Lower Clark Fork ERU had a very high risk of substantial mortality from insects, disease, stress, and large high-intensity fire occurrences.

Much of the Lower Clark Fork ERU is roaded and has been changed by timber harvest activities and fire exclusion. Consequently, in the Lower Clark Fork ERU the succession/disturbance regimes substantially shifted from a dominance of acceleration and maintenance regimes, to moderate-cycle and retrogressive cycle regimes.

Northern Cascades ERU

The Northern Cascades ERU is oriented along the crest of the Cascade Mountains in central Washington (map 3.3). This ERU has a very high relief (60 to 3,400 m) complex of low elevation valleys to higher elevation narrow valleys and steep mountains (map 3.17). Topography is generally steep and complex. Landforms include a mix of broad river valleys with breaks, and mountains and foothills with narrow valleys. Watersheds are mixed between downstream and headwater systems (map 3.21). The average precipitation across the ERU is relatively high, approximately 93 centimeters per year but with a steep gradient from an average of 24 centimeters per year at low elevations to an average of 190 centimeters per year at high elevations. The complex diversity of climate and topography has resulted in high vegetation diversity and a dynamic disturbance regime. The Northern Cascades ERU is primarily in ecoregion section M242C (map 3.1).

Climate is strongly influenced by the oceanic storm patterns from the west and the rain-shadow effect of the Cascade Mountains. There is a very steep gradient from the deep snowpacks and high precipitation on the Cascade crest to the Columbia River where there is little snow and low precipitation. Precipitation is primarily in the form of winter snows, spring rains, and summer thunder storms and showers. The upper elevations near the crest of the Cascades have a relatively low gradient from wet winter and spring conditions, to moist-to-dry summer and fall conditions with a short growing season. Moving away from the Cascade crest, the moisture gradient changes rapidly to a steep gradient of moist winter and spring conditions, to very dry summer and fall conditions with a moderately-long growing season. The Northern Cascades ERU has very dynamic succession/disturbance regimes because of its inherent productivity, steep climatic gradients, and complex topography. The dynamic succession/disturbance regimes are also associated with high carbon and moderate water stress on upland areas.

Fire exclusion, low- and mid-elevation timber-harvest activities, invasion by exotics, and livestock grazing practices have substantially altered fire regimes within the Northern Cascades ERU (maps 3.22 and 3.23). Fire severity generally shifted from a mixture of non-lethal and mixed, to lethal in the forest PVGs. This change was caused by the harvest of large, shade-intolerant tree species that were more fire-, insect-, disease-, and stress-resistant, as well as longer fire-return intervals that promoted the dominance of shade-tolerant species. In the non-forest PVGs (particularly in the eastern portion of the ERU), invasion by exotic annual grasses shifted the fire regimes from non-lethal to lethal, and increased the variability of fire frequency. When not grazed, areas invaded by annual exotic grasses are highly flammable and often experience more frequent fires.

From a regional perspective, the Northern Cascades ERU does not have a high risk of drought because most of the ERU receives more than 30 centimeters annual precipitation (map 3.24). At the landscape scale however, there are areas that have steep, southerly exposures and droughty environments. These droughty environments are typically dominated by the dry grass, dry shrub, or dry forest PVGs, and are susceptible to invasions by exotic plants, especially diffuse knapweed. Approximately 11 percent of BLM/FS lands and 18 percent of All lands in the Northern Cascades ERU are of high susceptibility to invasion by diffuse knapweed (table 3.47; map 3.37).

A moderate portion of the Northern Cascades ERU has had a history of livestock grazing on public lands (map 3.25). Many allotments were closed on public lands as a result of forest succession and the subsequent decline of forage availability. Rangeland conditions on public lands have generally improved since the mid-1900s, except with respect to exotic plant invasions in the drier PVGs. Riparian conditions have improved in some areas, but problems continue to exist in many areas relative to stream-channel conditions and the lack of shrub and herbaceous cover.

Road densities in the Northern Cascades ERU are high at low and mid elevations, and low to none at higher elevations (map 3.28). High road densities typically occur on subwatersheds with higher sensitivity to hydrologic regime disruption (map 3.29). Because forested watersheds are generally steeper and has less developed soils, they are generally more susceptible to erosion and sediment transport. Road densities are commonly high where forested watersheds have been developed for timber harvest. Poor road-drainage design or lack of drainage maintenance may cause slumps and washouts. Because of the narrow valley bottoms and draws of the Northern Cascades ERU, many roads were historically developed in close proximity to the stream network. Consequently, these roads often constrict the stream floodplain energy and have very short distances for sediment delivery.

The land-ownership pattern indicates that BLM/FS lands are fairly contiguous in the Northern Cascades ERU (map 3.30). There are large areas with relatively uniform BLM/FS ownership and some interspersed areas with mixed ownership patterns. A large portion of the BLM/FS lands has moderate and high risk of fire occurrence and associated high-intensity wildfires that could be difficult to suppress (map 3.31). These areas generally occur among the steeper, mid- and lower-elevation terrain of the dry and moist forest PVGs. Some areas at the landscape scale, particularly the break landforms, have high fire risk. The moderate and high risk have been related primarily to potential wildfire occurrence from lightning and human-caused ignition; dry spring, summer, and fall conditions; steep terrain; and heavy forest fuels that create the potential for severe fire behavior.

The Northern Cascades ERU has many areas that have high fuel accumulations, high potential for crown fire, and high potential of forest insect, disease, and stress-related mortalities at lower elevations (map 3.32). These areas have been associated with the dry forest and moist forest PVGs which have a high rate of NPP and high carbon stress. Timber harvest practices in these areas often removed most of the large, shade-intolerant trees that were more resistant to these mortality agents. The large, shade-intolerant trees have generally been replaced by smaller, shade-tolerant tree species that are susceptible to these types of mortality.

There are moderate and high risks related to the rural/wildland interface on the BLM/FS lands (map 3.33). At the landscape scale, high-risk areas often occur at the edge of the steep foothill or mountain environments. Rural developments are typically associated with the adjacent narrow valley landforms that are on the edge of, or interspersed with, the steep foothill or mountain landforms.

PVG composition did not change substantially between the historical and current periods in the Northern Cascades ERU (maps 3.11 and 3.12). Agricultural development occurred primarily in the dry shrub, dry grass, and dry forest PVGs and directly affected 7 percent of the ERU (table 3.77). The moist forest and cold forest PVGs dominated the area. The composition of PVGs on BLM/FS lands was similar, whereas Other lands were dominated by the moist forest PVG. Roads occupied approximately 2.3 percent of the ERU, and were nearly evenly distributed between BLM/FS lands and Other land ownerships.

The physiognomic type composition of the dry forest PVG is summarized across land ownership strata in tables 3.78 and 3.79. On All ownerships, the areal extent of the mid-seral forest physiognomic type was more than twice as high as the HRV maximum. Although the amount of the late-seral multi-layer forest physiognomic type was above the historical range, the late-seral single-layer forest type was well below in comparison to the HRV. There were contrasting trends for BLM/FS and Other land ownerships. The abundance of the early-seral forest type on BLM/FS lands was well above the upper end of the HRV, probably in response to recent historical clearcut and seed tree harvest practices. On Other lands, the areal extent of the early-seral forest physiognomic type was at the lower end of the HRV, probably in response to recent selective harvests.

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes. Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

On BLM/FS lands, the areal extent of the late-seral multi-layer forest physiognomic types was substantially above the upper end of the HRV, while on Other lands it was at the lower end of the HRV.

The late-seral single-layer physiognomic type followed similar trends on both BLM/FS and Other ownerships. In general, both early- and late-seral types shifted to mid-seral types because of fire exclusion, harvest activities, and insect, disease, and stress mortality associated with the overstory. In areas where the forests were harvested using clearcut and seed tree treatments, forest succession was accelerated toward mid-seral types as a result of regeneration planting activities. Fire exclusion eliminated the non-lethal and mixed fires that had maintained the late-seral single-layer physiognomic types and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer physiognomic types. Clearcut, seed tree, shelterwood, and group-selection timber-harvest activities commonly created a mosaic of early-seral patches with high down-fuel accumulations and fewer dead-standing or small, live tree structures. In the matrix areas surrounding the patches, the large trees and dead-standing trees were often selectively harvested. This combination of factors resulted in an overall landscape forest pattern that had high-risk conditions for fire, insects, disease, and stress mortalities.

In the dry forest PVG, the areal extent of the mid-seral physiognomic types dominated by shade-intolerant tree species was nearly twice as high as the upper limit of the HRV (table 3.79). This system was at very high risk of substantial mortality to insects, disease, and stress, as well as large, intense fires.

Trends in physiognomic types in the moist forest PVG of the Northern Cascades ERU were similar regardless of land ownership strata (tables 3.80 and 3.81). The areal extent of the early-seral forest type was generally well above the HRV for All ownerships. The amount of the late-seral single-layer forest type was well below the HRV. Departures from the HRV occurred as a result of timber harvest of late-seral forests and exclusion of fire.

The late-seral single- and multi-layer types shifted to mid-seral types due to harvest activities and insects, disease, and stress mortalities of the overstory. Fire exclusion eliminated non-lethal and mixed fires that had maintained late-seral single- and multi-layer types and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer types. Clearcut, seed tree, shelterwood, and group-selection timber-harvest activities commonly created a mosaic of early-seral patches with few standing dead or live tree structures, and high down-fuel accumulations. Typically, the large trees and dead-standing trees were selectively harvested in the matrix areas surrounding the regeneration harvest patches. This combination of factors resulted in an overall landscape forest pattern that had high-risk conditions for fire, insects, disease, and stress mortalities.

In the Northern Cascades ERU moist forest PVG, the areal extent of the mid-seral forest types dominated by shade-tolerant tree species was at the upper limit of the HRV for All ownerships, was low in comparison to the HRV for BLM/FS ownerships, and was high in comparison to the HRV for Other ownerships (table 3.81).

In the cold forest PVG of the Northern Cascades ERU, composition and physiognomic type varied considerably among ownership strata (tables 3.82 and 3.83). During the current period, the early-seral physiognomic type was substantially higher in areal extent than in the HRV for all ownership strata as a result of the extensive even-age harvesting (that is, clearcut and seed tree) that occurred within the subalpine forest. There were fairly even amounts of early-seral and mid-seral forest types on BLM/FS lands, while on Other ownerships the areal extent of the mid-seral forest type was almost twice that of the early-seral forest type. Across the entire ERU, there has been less clearcutting and wildfire occurrence on Other land ownerships. The amount of cold forest PVG land area in Other ownerships was small and nearly evenly distributed between (1) National Park/Tribal

Table 3.80—Current and historical period physiognomic types for the moist forest potential vegetation group (PVG) for Northern Cascades Ecological Reporting Unit (ERU).

Land Ownership Group[1]	Physiognomic Type	Current Year[2]	Historical Year 0	Historical Year 50	Historical Year 100

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

lands, where there had been little effect from harvest and fire, and (2) private industrial timber lands that had been substantially harvested. On BLM/FS and Other ownerships, the areal extent of the early-seral forest physiognomic type was well above the HRV. For All ownerships, the amount of the early-seral forest physiognomic type was almost twice the upper end of the HRV. The areal extent of the late-seral single-layer forest physiognomic type was essentially non-existent for all strata because of timber harvest activities and the exclusion of non-lethal and mixed-severity fires. The areal extent of the late-seral multi-layer forest type was substantially below the lower end of the HRV regardless of ownership strata. Again, it appears that timber harvests converted a substantial proportion of the late-seral multi-layer type to the early-seral forest type. In the native system, mixed and non-lethal fires had maintained the late-seral single-layer and multi-layer physiognomic types at relatively constant levels. Lethal fires generally cycled the mid-seral stages to the early-seral type.

Structural stage and shade tolerance of the Northern Cascades ERU cold forest PVG is summarized in table 3.83. The areal extent of the mid-seral shade-tolerant forest physiognomic types was within the

HRV for Other ownerships, whereas it was somewhat below the HRV for All and BLM/FS ownership strata. Historically, the shade-tolerant forests in the late-seral single-layer type were always rare; in the current period, they were practically nonexistent, possibly because of insect- and disease-related mortalities. This trend was relatively unique to the Northern Cascades ERU.

In response to the changes in regional and landscape conditions, the succession/disturbance regimes underwent a substantial shift from acceleration, moderate-cycle, and maintenance regimes to long-cycle and retrogressive cycle regimes. Some of the area was roaded, and has been changed by harvest activities and fire exclusion. Most of the area within wilderness and roadless areas had low probabilities for re-establishment of the native regimes given the existing constraints of using prescribed fire. There was a low probability of returning to the native system mixture of succession regimes without the congruent restoration of the stand structures and fuel conditions.

Northern Glaciated Mountains ERU

The Northern Glaciated Mountains ERU is located in northern Washington, Idaho, and Montana (map 3.3). This ERU has high relief (200 to 3,000 m) and complex landforms ranging from low-elevation broad valleys, to higher-elevation narrow valleys and breaks. The foothills and mountains developed primarily from glacial processes on volcanic, uplifted batholith granitic, and uplifted metasediments (map 3.17). Mountain ranges generally run from north to south with broad valleys in between. Watersheds are mixed between downstream and headwater systems (map 3.21). The Northern Glaciated Mountains ERU is primarily in ecoregion section M333D (map 3.1).

Climate is strongly influenced by the oceanic storm patterns from the west and the rain-shadow effect of the Cascade and Rocky Mountain ranges. There is a steep moisture gradient ranging from high precipitation zones of the mountain crests, to the low-elevation wide river valleys that receive little precipitation. However, this is variable depending on the geographic location of the mountain range and valley. Precipitation primarily falls in the form of winter snows, spring rains, and summer thunderstorms and showers. The upper elevations near the mountain crests have a relatively low gradient from wet winter and spring conditions, to moist-to-dry summer and fall conditions with a short growing season. The precipitation gradient changes rapidly at lower elevations on the mountain slopes, foothills, valleys, and breaks to a very steep gradient from moist winter and spring conditions to very dry summer and fall conditions with a moderately-long growing season. Precipitation is relatively high, averaging 82 centimeters per year, but ranges from 27 centimeters per year at low elevations to 315 centimeters per year at high elevations. The gradients of precipitation are not uniformly distributed throughout elevational ranges. Storms generally move from west to east, dropping moisture along orographic uplifts associated with mountain ranges. Valleys on the leeward side of the mountains often exist in a rain shadow. The east slopes of valleys are typically drier than their west slopes.

Soils in the Northern Glaciated Mountains ERU are highly diverse as a result of the diversity of parent materials and soil-forming processes associated with glacial deposition, glacially compacted till, volcanic ash fall, and erosion. The interaction of climate, parent material, and geomorphology has resulted in varied vegetation and disturbance regimes, and highly-complex biogeochemical processes. This ERU has dynamic succession/disturbance regimes because of its inherently high productivity, steep seasonal moisture gradients, complex topography, and high carbon stress and moderate water stress in upland areas.

Fire exclusion, timber harvest activities at low and mid elevations, invasion by exotic plants, and livestock grazing practices changed the fire regimes between the historical and current periods (see maps 3.22 and 3.23). Fire severity shifted from a mixture of lethal, mixed, and non-lethal, to mostly lethal in the forest PVGs. The harvest of large, shade-intolerant, fire-, insect-, disease-, and stress-resistant tree species, and the extended fire-return intervals promoted the dominance of shade-tolerant species. Shade-tolerant species are generally not as resistant to fire, insect, disease, and stress. In the non-forest PVGs, and in the herbaceous physiognomic type of the dry forest PVG, exotic forbs such as spotted knapweed, leafy spurge, sulfur cinquefoil, and diffuse knapweed became prevalent. Areas dominated by these species were relatively fire resistant, and had reduced fire frequencies.

From a regional scale perspective, the Northern Glaciated Mountains ERU is not highly susceptible to drought (map 3.24). However, at the landscape scale, there are areas located on steep topographic settings with southerly exposures that tend to have a droughty environment. These droughty environments are typically dominated by the dry forest, dry grass, or dry shrub PVGs, and are susceptible to invasion by exotic plants. Exotic forbs, in particular spotted knapweed, leafy spurge, sulfur cinquefoil, and diffuse knapweed, have been problematic in this ERU. Approximately 33, 13, and 15 percent of the Northern Glaciated Mountains

ERU is of high susceptibility to invasion by spotted knapweed, leafy spurge, and diffuse knapweed, respectively (table 3.47; maps 3.35, 3.36, and 3.37).

A moderate portion of this ERU has had a history of livestock grazing on public lands (map 3.25). Many allotments were closed on public lands as a result of forest succession and the subsequent decline of available forage. Rangeland conditions on public lands have generally improved since the mid-1900s, except where exotic vegetation has invaded the dry grass and dry shrub PVGs. Although riparian conditions have improved in some areas, problems continue to exist in many areas relative to stream channel conditions and the lack of shrub and herbaceous cover.

Road densities in the Northern Glaciated Mountains ERU range from high to moderate at low and mid elevations, and low to none at higher elevations (map 3.28). High and moderate road densities typically occur on watersheds that are more susceptible to the disruption of hydrologic regimes (map 3.29). In particular, the Northern Glaciated Mountains ERU has substantial amounts of moist-to-wet soils, which are subject to slumps and earth flows. Where forested watersheds have been developed for timber harvest, road densities are commonly moderate to high.

The pattern of BLM/FS and Other land ownerships within the Northern Glaciated Mountains ERU is fragmented (map 3.30). Typically, there are areas with relatively uniform BLM/FS ownership interspersed with areas of mixed, mosaic, and Other ownership patterns. A large portion of the BLM/FS lands have moderate risk of fire occurrence and associated high-intensity wildfires that could be difficult to suppress (map 3.31). These areas are mostly associated with mid and lower elevations, and with steep terrain comprised by dry and moist forests.

There are areas at the landscape scale, particularly the break landforms, that have high fire risks. The high risks have been related primarily to potential wildfire occurrence from lightning and human-caused ignitions; dry spring, summer, and fall conditions; complex steep terrain; and heavy forest fuels that create the potential for severe fire behavior. At lower elevations, the Northern Glaciated Mountains ERU contains areas with high fuel accumulations, high potential for crown fire, and high forest insect-, disease-, and stress-related mortalities (map 3.32). These areas have been associated with the dry and moist forest PVGs that have high NPP and high carbon stress. Historical timber harvest practices removed most of the large, shade-intolerant trees that are more resistant to these types of mortality. These large, shade-intolerant trees have typically been replaced by smaller, shade-tolerant tree species that are more susceptible to the above-mentioned mortality agents.

Moderate and high fire risks occur in the rural/wildland interface on the BLM/FS lands (map 3.33). At the landscape scale, the high-risk areas often occur at the edge of the steep foothill, mountain, or break environments. Rural developments are typically associated with the adjacent valley landforms.

Between the historical and current periods, PVG composition did not change substantially in the Northern Glaciated Mountains ERU (table 3.84, map 3.11 and 3.12). Agricultural development occurred at the expense of the dry shrub, dry grass, and dry forest PVGs, and directly affected 13 percent of the ERU. The moist forest and dry forest PVGs dominated the ERU as a whole, as well as the PVG composition of Other land ownerships. The PVG composition on BLM/FS lands was dominated by the moist forest. Approximately 2.7 percent of the ERU was converted to roads. Other land ownerships contained nearly 25 percent more roads than did BLM/FS lands.

Field experience in the Northern Glaciated Mountains ERU suggested that the extent of BLM/FS lands composed of the dry forest PVG had probably been underestimated. Inaccurate estimation of the dry forest extent may have been due to the fact that, on BLM/FS lands, these PVGs commonly occur in small patches within the complex terrain of the Northern Glaciated

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes. Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

Mountains ERU. Thus, even though our data indicated that the dry forest PVG composed less than 5 percent of BLM/FS lands, discussion of this PVG was warranted with respect to the changes of physiognomic types and associated succession/disturbance regimes.

The physiognomic type composition of the dry forest PVG varied among ownership strata in the Northern Glaciated Mountains ERU (tables 3.85 and 3.86). The areal extent of the early-seral forest physiognomic type was generally at the lower end of the HRV for All lands, substantially higher than the HRV on BLM/FS lands, and below the HRV on Other lands. These inconsistent trends occurred because timber harvest practices on much of the BLM/FS lands used mostly cycling treatments, such as clearcuts or seed tree cuts. However, on Other lands the emphasis was on selective harvest treatments. The areal extent of the mid-seral forest physiognomic type was two to three times as high as the HRV for all ownership strata, due to the retrogression of late-seral multi- or single-layer forest types to the mid-seral forest type. This retrogression was the result of selective harvesting of larger trees, fire exclusion, and the associated insect, disease, and stress mortalities of the residual, large, overstory trees. The late-seral multi-layer forest area was very low and the late-seral single-layer forest area was essentially non-existent in comparison to the HRV, regardless of land ownership strata.

In general, both the early- and late-seral physiognomic types shifted to the mid-seral physiognomic types because of fire exclusion, harvest activities, insects, disease, and stress mortalities in the overstory layer. In areas where the forests had been harvested using clearcut, seed tree and planting treatments, forest succession was accelerated toward mid-seral types faster than in the native system. Fire exclusion eliminated the non-lethal and mixed fires that had maintained the late-seral single- and multi-layer physiognomic types and thinned shade-tolerant tree species in the early-, mid-, and late-seral multi-layer physiognomic types. Clearcut, seed tree, shelterwood, and group-selection timber-harvest activities commonly created a mosaic of patches that comprised early-seral types, high down-fuel accumulations, and lacked dead and live structures. In the matrix areas surrounding the patches, the large trees and dead-standing trees were often selectively harvested. This combination of factors resulted in an homogenization of landscape forest patterns and increased the risks of fire, insect, disease, and stress mortalities.

The amount of the mid-seral physiognomic types in the dry forest PVG—which was dominated by both shade-tolerant and shade-intolerant tree species—was much higher than the HRV (table 3.86). This system was at very high risk of substantial mortality to insects, disease, stress, and large, high-intensity fires.

Trends in physiognomic type composition of the moist forest PVG of the Northern Glaciated Mountains ERU were similar in all ownership strata (tables 3.87 and 3.88). The areal extent of the early-seral forest physiognomic type was below the HRV because of fire exclusion and reduction of the early succession timeframe by advanced regeneration plantings. The areal extent of the mid-seral forest physiognomic type was twice the HRV. This was attributable to the lack of acceleration disturbances that would have moved the mid-seral forest type into the late-seral types; rapid succession of early-seral types into mid-seral stages; and the retrogression of late-seral forest types into mid-seral stages. The retrogression of late-seral forest types was caused by a lack of maintenance disturbances, loss of western white pine to blister rust, and selective harvesting of large, shade-intolerant trees that were more fire-, insect-, disease-, and stress-resistant.

The areal extent of the late-seral multi-layer forest physiognomic types was substantially below the HRV, and the late-seral single-layer physiognomic type was essentially non-existent. In areas where the forests were harvested using clearcut, seed tree, and planting treatments, forest succession was accelerated toward mid-seral types at a faster rate than in the native system.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

Fire exclusion had eliminated the non-lethal and mixed-fire regimes that had maintained the late-seral single- and multi-layer physiognomic types, and thinned shade-tolerant tree species in the early-, mid-, and late-seral multi-layer physiognomic types. Clearcut, seed tree, shelterwood, and group-selection timber-harvest activities created a mosaic of early-seral patches with fewer live and dead trees, and high down-fuel accumulations. In the matrix areas surrounding the patches, the large trees and dead-standing trees were often selectively harvested. Consequently, landscape patterns were largely homogenized, increasing the risks of fire, insect, disease, and stress mortalities.

In general, the trends of shade-intolerant and shade-tolerant species were consistent with the physiognomic type trends of the moist forest PVG of the Northern Glaciated Mountains ERU (table 3.88). In the mid-seral physiognomic type, the amount of shade-tolerant forest was very high, relative to the HRV. The loss of western white pine from this system due to blister rust infestations resulted in the loss of a fast-growing, dominant tree in moist environments. This system had very high risks of substantial mortality from insects, disease, stress, and large high-intensity fires.

[3]+ = < 0.5%.

In response to the changes in regional and landscape conditions, the primary change in succession/disturbance regimes appears to have been a shift from moderate and accelerated cycles, to long and retrogressive cycles. Given the limitations of prescribed fire and the effects of blister rust on western white pine, we believe that restoration opportunities are limited in many of the wilderness and roadless areas. The current prescribed natural fire program experiences only a limited number of ignitions and a limited number of prescribed natural fires. The small number of ignitions are the result of efficient fire-suppression efforts. Wilderness and roadless areas have many restoration opportunities provided that a prescribed fire program allows an adequate number of ignitions. Restoration of roaded areas will require modification of landscape patterns, fuel conditions, and the promotion of western white pine and fire. Trends for the cold forest PVG are displayed in tables included in appendix 3-N.

Northern Great Basin ERU

The Northern Great Basin ERU is located primarily in Oregon (map 3.3). This ERU has a low relief (1,200 to 2,900 m) complex of wide valleys and plains with interspersed breaks and scattered foothills and mountains (map 3.17). Topography ranges from gentle to rugged as a result of differing types of volcanic and erosional processes. Landforms include a mix of valleys, plains, breaks, foothills, and a few scattered small mountain ranges, with a mix of headwater and downstream watersheds (map 3.21). The ERU is primarily in ecoregion section 342B (map 3.1).

Precipitation averages 32 centimeters per year (range = 23 to 82 cm). Most of the ERU is within 5 centimeters of the average. Areas on the low end of the precipitation range are generally confined to the desert areas; areas at the upper end of the range are confined to the mountainous areas. Climate is strongly influenced by the rain-shadow effect of the Cascade Mountains to the west and intermountain storm patterns from the southwest. Precipitation primarily falls in the form of winter rain or snow and some spring rains. Frequent winds and high temperatures during the growing season create high rates of evapotranspiration and soil surface moisture desiccation. There is a moderately steep gradient from relatively moist winter and spring conditions, to very dry summer and fall conditions. Soils are diverse due to the variation in type of parent material, effects of periglacial processes, soil depth, salinity, clay accumulation quantities, and presence of impermeable subsurface layers. However, the number of plant species able to dominate in this type of environment is relatively low. Consequently, vegetation diversity is fairly low. Net primary productivity is low, nutrient cycling is moderate, carbon stress is low, and water stress is high.

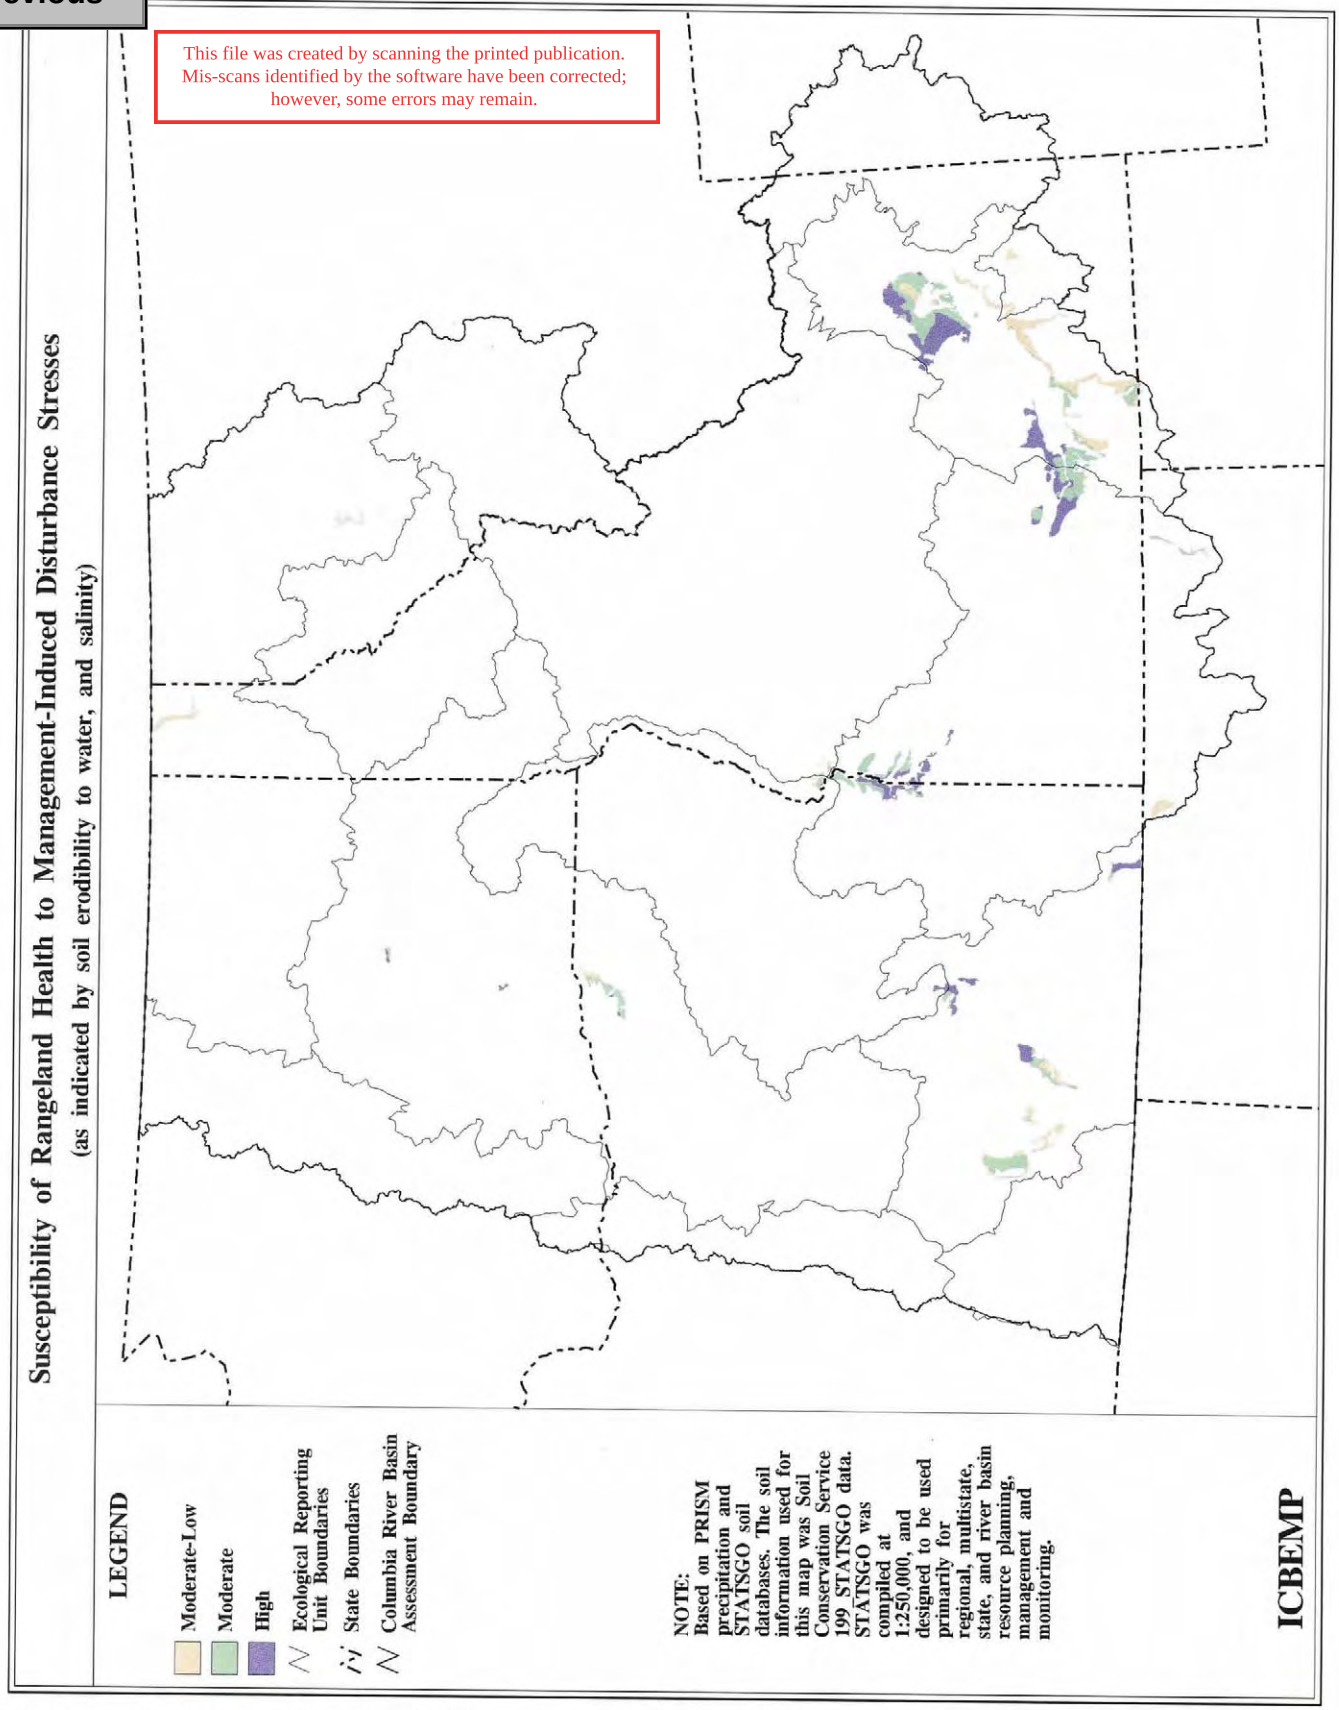
There were substantial changes in fire regimes in the Northern Great Basin ERU primarily as a result of exotic annual grass invasions, excessive livestock grazing pressure, and fire exclusion (maps 3.22 and 3.23). Exotic annual grasses are more flammable than the native vegetation, but excessive livestock grazing pressure normally reduced fuels to levels where fires would not carry. In contrast to ERUs that had more moisture, more forest vegetation, and higher fire occurrence during drought years, the Northern Great Basin ERU typically has experienced fire events during years that produce higher amounts of fine-grass fuels. In the forest PVGs, fire severity generally shifted from non-lethal and mixed, to lethal. In the non-forest PVGs, the primary change was increased variability in fire intervals.

From a regional-scale perspective, the Northern Great Basin ERU has substantial area that receives less than 30 centimeters of precipitation annually (map 3.24). Drought was frequent, occurring 18 percent of the years from 1895 to 1994. Conversely, there were periods of above-normal precipitation two or more years in succession (table 3.38; climate division: Oregon South Central). The droughty environment of the Northern Great Basin reduces the potential for successful restoration efforts in non-forest and dry forest PVG areas which have been altered by exotic vegetation or excessive livestock grazing pressure.

The Northern Great Basin ERU has had a long history of livestock grazing on both private and public lands (map 3.25). Excessive livestock grazing pressure in the late-1800s was documented in this ERU by Griffiths (1902). Reduction in palatable shrubs, grasses, and forbs in the valleys, foothills, and mountains (such as the Steens Mountain area) was evident by 1901. Most rangeland riparian areas were already in a very degraded condition by the turn of the century. Many stream and riverbanks had typically been downcut to the extent that their associated riparian area no longer existed. By the mid-1900s however, some improvements in rangeland conditions and associated watershed conditions were apparent.

During the last 100 years, invasion and spread of exotic plants has been extensive. Halogeton (*Halogeton glomeratus*), cheatgrass, medusahead, Scotch thistle (*Onopordum acanthium*), Mediterranean sage (*Salvia aethiopis*), perennial pepperweed (*Lepidium latifolium*), and dalmatian toadflax were prevalent in portions of the Northern Great Basin ERU in the current period. Approximately 64 percent of All lands, and 66 percent of BLM/FS lands in this ERU were of high susceptibility to invasion by cheatgrass (table 3.47; map 3.26). Invasions by these exotic plants have caused a decline in native biodiversity, particularly in the riparian and the dry shrub PVGs. Many upland rangelands have been seeded to desirable, exotic, perennial grasses, particularly crested wheatgrass, which in some areas also contributed to the decline of biodiversity. Even though there is little similarity in species composition relative to the native communities, the seeded exotic perennial-grass communities are more similar in structure and disturbance regimes than are exotic annual-grass communities. Currently, areas that support native plant communities without much exotic vegetation continue to persist in the Northern Great Basin ERU. These areas are typically located in inaccessible areas, or are devoid of open water and therefore have little history of excessive livestock grazing pressure.

Road densities in the Northern Great Basin ERU are generally low to moderate with few areas of very low and none (map 3.28). Most of the ERU has watersheds that are in relatively good condition (map 3.29). Soils susceptible to erosion by wind are extensive in the Northern Great Basin ERU (table 3.46; maps 3.18, 3.19, and 3.34). Saline soils, soils susceptible to shrinking or swelling from drying or wetting, and soils susceptible to erosion by water, are less extensive but still prevalent (table 3.46; maps 3.19, 3.20, 3.34, 3.41, 3.42, and 3.43).



Patterns of BLM/FS and Other land ownerships are moderately fragmented. A relatively high proportion of the Northern Great Basin ERU is under BLM/FS ownership (map 3.30). Most of the breaks, plains, foothills, and mountains are in uniform BLM/FS ownership, with mixed and mosaic land ownerships in the valley areas. Approximately 50 percent of the BLM/FS lands has moderate risk of fire occurrence and associated high-intensity wildfires that could be difficult to suppress (map 3.31). These fires generally occur in areas with a mosaic of dry shrub and dry forest PVGs. There are some areas at the landscape scale, particularly the break landforms, that have high fire risks.

The Northern Great Basin ERU has a very small component of forest and woodland that has high fuel accumulations, and high potential for crown fires, forest insects, diseases, and stress-related mortalities (map 3.32). Moderate and high risks are due to potential wildfire occurrence from lightning or human-caused ignition; dry spring, summer, and fall conditions; complex break or foothill terrain; and flammable annual grass fuels intermingled with dry shrub PVGs which created the potential for severe fire behavior. There are no substantial risks related to the rural/wildland interface on the BLM/FS lands (map 3.33). At the landscape scale, there are some high-risk areas adjacent to small rural developments. These communities often occur at the edge of valleys adjacent to steep break or foothill environments.

Map 3.41—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil erodibility to water, and salinity. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having these specific soil-property indicators: an erodibility factor (K factor) exceeding 0.37, and salinity of 8 to 16 millimhos per centimeter (mmhos/cm); none of the other three, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Map 3.42—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil salinity. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having salinity of 8 to 16 millimhos per centimeter (mmhos/cm); none of the other four, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Map 3.43—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil salinity and potential for soil to shrink or swell from drying or wetting. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having these specific soil-property indicators: salinity of 8 to 16 millimhos per centimeter (mmhos/cm), and a high shrink-swell potential (SSP); none of the other three, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

Rural developments are typically associated with the adjacent valley and plain landforms that are on the edge of, or interspersed with, the steep, complex topography of the break landforms. The break landforms are typically the BLM/FS lands or other public lands.

Between the historical and current periods, PVG composition did not change substantially in the Northern Great Basin ERU (table 3.89; maps 3.11 and 3.12). Only 3 percent of the ERU was developed for agriculture. Agricultural conversion primarily affected the dry forest, dry shrub, and riparian shrub PVGs. The dry shrub PVG dominated all ownership strata in the ERU. Approximately 1.8 percent of the total area was roaded, of which 1.3 percent was on BLM/FS lands and 0.5 percent was on Other lands.

The historical to current period trends in physiognomic type composition of the dry shrub PVG were similar for all ownership strata (table 3.90). Exotic herbland types were furthest outside the HRV as these species were not present in native systems. The amount of area occupied by exotic herblands was substantially underestimated for the current period. Exotic vegetation, especially cheatgrass, was scattered throughout the dry shrub PVG within the upland herbland and upland shrubland physiognomic types. The native system was generally dominated by a shifting mosaic of upland herbland and upland shrubland physiognomic types that were maintained by frequent non-lethal and mixed fires. As a result of excessive livestock grazing pressure and fire exclusion, the upland herbland physiognomic type declined, whereas the upland shrubland physiognomic type increased. Thus, the shifting mosaic that existed historically was generally replaced by a relatively static mosaic of annual grass patches and patches of shrubs mixed with annual grasses.

The historical trends of physiognomic type composition in the dry forest PVG were similar for all ownership strata (tables 3.91 and 3.92). The amount of the exotic herbland type was substantially underestimated because of forest overstory cover and misidentification as early-seral vegetation. The amount of the late-seral multi-layer forest physiognomic type was well above the HRV. The amount of the late-seral single-layer forest physiognomic type occurred substantially below or at the low end of the HRV. These conditions related primarily to the exclusion of non-lethal and mixed-underburn fires. There were no substantial timber harvest effects in this ERU. The environments of the dry forest were very dry and succession to multi-layer physiognomic types in the absence of fire was very slow.

In essence, the trends toward (1) decreases in the early-seral type as a result of exclusion of cycling fires, (2) large increases in the mid-seral types as a result of retrogression from the late-seral multi-layer types and succession to the mid-seral types, and (3) loss of the late-seral single-layer types, occurred in this ERU at a very slow rate. The rate was slow because sites were very dry and lacked recent harvesting of the large shade-intolerant overstory trees. In general, the dry forest had fairly low risks of fire-, insect-, disease-, and stress-related mortalities. The amount of the mid-seral forest types, dominated by shade-intolerant tree species, was generally above the lower limit of the HRV, while the amount of the late-seral forests was substantially above the HRV (table 3.92).

In response to the changes in regional and landscape conditions on forest and rangelands, the succession/disturbance regimes went through a substantial shift from moderate-cycle and maintenance regimes to retrogressive-cycle regimes, primarily due to extensive livestock grazing pressure, fire exclusion, and secondarily to exotic vegetation invasion. Given the lack of technology related to long-term rehabilitation of areas invaded by exotic forbs or annual grasses, there is a low probability of restoring native succession/disturbance regimes. However, with improved grazing practices and restoration of the more productive (generally more mesic) environments, much of the native composition and structure could be restored. Riparian environments have more potential for restoration given stabilization of the hydrologic regime.

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes.

Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

Owyhee Uplands ERU

The Owyhee Uplands ERU is located primarily in southwestern Idaho and southeastern Oregon (map 3.3). This ERU has relatively high relief (640 to 3,200 m) with a complex of plains interspersed with valleys and breaks, and scattered foothills and mountains (map 3.17). Topography is generally rugged as a result of different volcanic and erosional processes. Landforms include a mosaic of plains, valleys, breaks, foothills, and mountain ranges, with a mix of headwater and downstream watersheds (map 3.21). The Owyhee Uplands ERU is primarily in ecoregion section 342C (map 3.1).

The precipitation average for the ERU is 29 centimeters per year (range = 19 to 67 cm). Precipitation for most of the area is within 5 centimeters of the average. Areas on the low end of the range are generally confined to the desert and break areas, while areas at the upper end of the range are confined to the mountainous areas. Climate is strongly influenced by the rain-shadow effect of the Cascade Mountains to the west and intermountain storm patterns from the southwest. Precipitation primarily comes in the form of winter rain or snow, and some spring rains.

Frequent winds and relatively high temperatures during the growing season cause high rates of evapotranspiration and soil surface moisture desiccation. There is a moderately steep gradient from somewhat moist winter and spring conditions, to very dry summer and fall conditions with a long growing season. Soils are quite complex and varied in parent material type, periglacial process effects, depth, salinity, quantity of clay accumulation, and presence of impermeable subsurface layers. Few plant species dominate this environment, and vegetation diversity is fairly low. Net primary productivity is low, nutrient cycling is moderate, carbon stress is low, and water stress is high.

There were substantial changes in fire regimes between the historical and current periods, primarily resulting from the invasion of exotic annual grasses, excessive livestock grazing pressure, and fire exclusion (maps 3.22 and 3.23). Exotic annual grasses are more flammable than the native vegetation, but excessive livestock grazing pressure can reduce fuels to levels unable to carry fires. In contrast to ERUs that have greater moisture levels, more forest vegetation, and high fire occurrence during drought years, the Owyhee Uplands ERU typically has fires during moist years that produce higher amounts of fine-grass fuels. In the forest PVGs, fire severity has generally shifted from nonlethal and mixed, to a lethal regime. In the nonforest (rangeland) PVGs, the primary change has been a greater variability of fire intervals.

From a regional-scale perspective, a substantial proportion of the Owyhee Uplands ERU receives less than 30 centimeters of annual precipitation (map 3.24). Drought is frequent, occurring 16 to 20 percent of the time during the period 1895 to 1994 for this ERU (table 3.38; climate divisions: Oregon Southeast, Idaho Southwest Highlands, Idaho Central Plains, and Idaho Southwest Valleys). Conversely, only six to nine periods of above-normal precipitation, two or more years in succession, were detected from 1895 to 1994 (table 3.38). The droughty conditions of the Owyhee Uplands ERU reduce the potential for successful restoration efforts within the non-forest PVGs that have been altered by the invasion of exotic plants or excessive livestock grazing pressure.

The Owyhee Uplands ERU has had a long history of livestock grazing on both private and public lands (map 3.25). Excessive livestock grazing pressure was observed in this ERU in the late-1800s (Hodgeson 1948, in Yensen 1981; Piemeisel 1938, in Yensen 1981). Reduction in palatable shrubs, grasses, and forbs in the valleys, foothills, and mountains was evident by 1900. Most rangeland riparian areas were in a degraded condition by the turn of the century. By the mid-1900s however, some improvements in rangeland conditions and associated watershed conditions were apparent.

During the last 100 years, the invasion and spread of exotic plants has been extensive in the Owyhee Uplands ERU. Currently, cheatgrass, medusahead,

Scotch thistle, rush skeletonweed (*Chondrilla juncea*), Russian knapweed (*Centaurea repens*), whitetop, spotted knapweed (*Centaurea maculosa*), and diffuse knapweed are prevalent in portions of the ERU. Approximately 67 percent of All lands and 73 percent of BLM/FS lands in this ERU are of high susceptibility to invasion by cheatgrass (table 3.47; map 3.26). At present, a substantial portion of the ERU has cheatgrass and/or medusahead as either a monoculture or as an understory component (Pellant and Hall 1994). Consequently, native biodiversity has declined, particularly in the riparian and dry shrub PVGs. In addition, many upland rangelands have been seeded to exotic perennial grasses, especially crested wheatgrass, which in some areas has contributed to a reduction in biodiversity. Even though there is little similarity in species composition relative to the native communities, the structure and disturbance regimes of the seeded exotic perennial grass communities are more similar to the native communities than are the exotic annual grass communities. Some areas, typically those that were inaccessible to livestock use, continue to support native plant communities and do not have a prevalent exotic plant component.

Road densities in the Owyhee Uplands ERU are mostly low to moderate with a few areas having very low to none (map 3.28). Most of this ERU has watersheds that are in relatively good condition (map 3.29). Soils susceptible to erosion by water and wind, soils susceptible to shrinking or swelling from drying or wetting, and saline soils are extensive in the Owyhee Uplands ERU (table 3.46; maps 3.18, 3.19, 3.20, 3.34, 3.38, 3.39, 3.40, 3.41, and 3.42).

BLM/FS ownerships comprise a relatively large proportion of the Owyhee Uplands ERU. The pattern of BLM/FS and Other ownerships is moderately fragmented (map 3.30). Most of the breaks, plains, foothills, and mountains are in uniform BLM/FS ownership with mixed and mosaic ownerships in the valley areas. Approximately 70 percent of the BLM/FS lands have moderate risks of fire occurrence and associated high-intensity wildfires that could be difficult to suppress (map 3.31). These risk areas are generally located where a mosaic of dry shrub and dry forest PVGs occur. There are areas at the landscape scale, particularly the break landforms, that have high fire risk.

The Owyhee Uplands ERU has a very small component of dry forest and woodlands with high fuel accumulations, and high potential for crown fires, forest insects, diseases, and stress-related mortalities (map 3.32). Moderate and high risks have been related primarily to potential wildfire occurrence from lightning or human-caused ignition; dry spring, summer, and fall conditions; complex break or foothill terrain; and flammable annual grass fuels intermingled with dry shrub that create the potential for severe fire behavior. There are no substantial risks related to the rural/wildland interface on the BLM/FS lands (map 3.33). At the landscape scale, there are some high-risk areas adjacent to small rural developments. These communities are typically associated with the adjacent valley and plain landforms that are on the edge of, or interspersed with, the steep and complex topography of the break landforms. The break landforms are typically located on BLM/FS lands or other public lands.

PVG composition changed substantially in the Owyhee Uplands ERU between the historical and current periods, due to agricultural development (table 3.93; maps 3.11 and 3.12). Thirteen percent of the lands were converted to agriculture, which were primarily developed from the dry shrub, riparian shrub, and cool shrub PVGs. Regardless of ownership strata, the dry shrub PVG dominated the ERU, followed by the cool shrub PVG. Approximately 1.5 percent of the total area has been developed into roads, which are nearly evenly distributed between BLM/FS and Other land ownerships.

The physiognomic type composition of the dry shrub PVG was similar for all ownership strata (table 3.94). The exotic herbland type was far outside the HRV since they were not represented in the native systems. The areal extent of the exotic

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

herbland physiognomic type was substantially underestimated for the current period because of misidentification as the upland herbland physiognomic type, and presence of the upland shrubland physiognomic type in the understory. Exotic vegetation composition may have been as high as 50 percent of the upland herbland physiognomic type. The historical system was generally dominated by a shifting mosaic of upland herbland and upland shrubland types that were maintained by frequent non-lethal and mixed fires. As a result of the invasion of exotic annual grasses and forbs, excessive livestock grazing pressure, and fire exclusion, this shifting mosaic was generally replaced by a relatively static mosaic of patches of annual grass, patches of shrub/annual grass, and some remnants of native upland shrub/bunchgrass patches.

The physiognomic type composition and trends of the cool shrub PVG were similar for all ownership strata (table 3.95). The areal extent of the exotic herbland physiognomic type was far outside the HRV. The areal extent of exotic herbland types was substantially underestimated for the current period because of difficulty in differentiating exotic forbs, perennial grasses, and annual grasses from the native upland herbland and upland shrubland types. The exotic component could have been as high as 35 percent of the upland herbland type and was common in much of the upland shrubland type. The areal extent of the mid-seral woodland physiognomic type exceeded the HRV, primarily because of the encroachment of western juniper (*Juniperus occidentalis*) into the cool shrub PVG. The historical systems were generally dominated by a shifting mosaic of upland herbland and upland shrubland types maintained by a mix of frequent non-lethal, mixed, and lethal fires. As a result of the invasion of exotic annual grasses and forbs, excessive livestock grazing pressure, seeding of desirable exotic-perennial grasses, and fire exclusion, this shifting mosaic was generally replaced by a relatively static mosaic of patches of exotics, patches of upland shrubland types, remnants of native upland shrubland/bunchgrass types, and woodlands dominated by western juniper.

Due to the invasion of exotic plants, excessive livestock grazing pressure, and fire exclusion, the succession/disturbance regimes of this PVG underwent substantial shifts from moderate-cycle and maintenance regimes, to retrogressive and short-cycle regimes. Given the lack of technology related to long-term rehabilitation of areas invaded by exotic species, there is little chance of restoring native succession/disturbance regimes. However, with improved grazing practices and restoration of the more productive environments (that is, more mesic), much of the existing composition and structure could be restored. Riparian environments have more potential for restoration, given that the hydrologic regime is stabilized.

Snake Headwaters ERU

The Snake Headwaters ERU is located in southeastern Idaho and western Wyoming (map 3.3). This ERU has moderate relief (1,300 to 3,700 m) with a complex of wide valleys, foothills, and mountains (map 3.17). The ERU contains a mixture of headwater and downstream watersheds (map 3.21). Erosional, fluvial, and glacial processes have created a complex topography. The ERU is primarily in ecoregion sections M331A and M331D (map 3.1).

Precipitation averages 71 centimeters per year (range = 26 to 131 cm). The precipitation and topographic gradients support moderately diverse vegetation. Climate is strongly influenced by oceanic storms from the west, the continental climates to the east, and intermountain storm patterns from the southwest. Precipitation primarily falls as winter snows, spring rains, and summer thunder storms. The gradient from relatively moist spring conditions, to dry summer and fall conditions is moderately steep and the growing season is moderately long. Consequently, the inherent rate of NPP and nutrient cycling is moderately high, as is the carbon and water stress on upland areas.

Substantial changes in fire regimes occurred between the historical and current periods, primarily as a result of fire exclusion (maps 3.22 and 3.23).

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

Fire severity generally shifted from non-lethal and mixed to lethal regimes, and non-lethal to mixed regimes in the forest PVGs, and fire-return intervals became longer. In the non-forest PVGs, fire severity generally shifted from mixed to lethal, and fire-return intervals increased due to the removal of fine fuels by livestock grazing, encroachment of conifers, and fire exclusion.

From a regional perspective, the Snake Headwaters ERU is generally not in a high-risk drought climate; nearly all of the ERU averages greater than 30 centimeters annual precipitation (map 3.24). Therefore, most of the non-forest PVGs that have been altered by exotic plant invasions or by excessive livestock grazing pressure have a fairly high restoration potential. However, at the landscape scale, steep topographic settings with southerly exposures and thin soils tend to be droughty environments (approximately 5% of the area).

There has been a long history of livestock grazing on the public lands of the Snake Headwaters ERU (map 3.25). Since the late-1800s, much of the public land-ownership area that was in allotments has been grazed by sheep and cattle. Substantial improvements in range conditions and associated watershed conditions have occurred since the mid-1900s. Prevalent and important exotic plants in the Snake Headwaters ERU include dyers woad (*Isatis tinctoria*), spotted knapweed, and leafy spurge. The current period dry grass and riparian woodland PVGs were of high susceptibility to invasion by spotted knapweed and leafy spurge. Approximately 31 and 14 percent of All lands in the Snake Headwaters ERU were of high susceptibility to invasion by spotted knapweed and leafy spurge, respectively. Similarly, 18 and 3 percent of the BLM/FS lands within the ERU were of high susceptibility to invasion by spotted knapweed and leafy spurge (table 3.47; maps 3.35 and 3.36).

Road densities generally range from low to none in this ERU, but there are some areas with moderate and high densities (map 3.28). Because of its steep topography and moist-to-wet soils, much of the Snake Headwaters ERU has sensitive watersheds. Some of the watersheds on the outer edges of the ERU are in degraded conditions due to moderate-to-high road densities located in sensitive watersheds (map 3.29).

The pattern of BLM/FS and Other land ownerships is moderately fragmented in the Snake Headwaters ERU (map 3.30). A substantial component is in uniform BLM/FS lands, whereas mixed and mosaic patterns occur on the western side of the ERU. Very few of the BLM/FS lands have moderate or high risks of fire occurrence and associated high-intensity wildfires, which could be difficult to suppress (map 3.31). At the landscape scale, some of the area has high fire risks, particularly the lower-elevation, steeper, foothill topography. In addition, a minor component of the western edge of the Snake Headwaters ERU also has high fuel accumulations, high potential for crown fire, and high forest insect-, disease-, and stress-related mortalities (map 3.32). These areas are typically dry forests that have high carbon and water stress. There are also substantial risks to large areas of lodgepole pine in the cold forest PVG associated with mountain pine beetle mortality. There are moderate fire risks related to the rural/wildland interface on the BLM/FS lands that are adjacent to rural developments (map 3.33). At the landscape scale, high-risk areas are often at the edge of the steep foothill environments. Rural developments are typically associated with the bench or valley landforms that are on the edge of, or interspersed with, the steep topography of the foothill landforms. The foothill landforms are typically located on BLM/FS lands.

From the historical to the current period, PVG composition changed substantially in the Snake Headwaters ERU, the result of agricultural development on approximately 10 percent of the area (table 3.96; maps 3.11 and 3.12). Most of the agricultural development occurred in the dry shrub, dry forest, cold forest, and riparian woodland PVGs. In the current period, the ERU was dominated by the cold forest, riparian woodland, and dry forest PVGs (45, 18, and 17%, respectively), with lesser amounts of the dry grass PVG. BLM/FS lands were dominated by the cold forest

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes.

Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

PVG, whereas Other lands were dominated by the cold forest, dry shrub, and riparian woodland PVGs. Approximately 1.8 percent of the total ERU area was in roads of which 1.0 percent occurred on Other lands and 0.8 percent occurred on BLM/FS lands.

Although the dry shrub PVG composed less than 5 percent of BLM/FS lands in the Snake Headwaters ERU, we included a discussion of its physiognomic type changes, with respect to succession/disturbance regimes, because we believe that the areal extent of the dry shrub PVG on BLM/FS lands was underestimated. The dry shrub PVG commonly occurs in small patches within the complex terrain found throughout the Snake Headwaters ERU. Further, underestimations of the dry grass and cool shrub PVGs may have also occurred in this ERU, but it was determined that the trends of the dry shrub PVG are similar enough to provide an example of what has potentially occurred on the other non-forest PVGs.

The physiognomic type composition of the dry shrub PVG is summarized in table 3.97. The exotic herbland types were furthest outside the HRV, particularly on BLM/FS lands. However, the amount on Other lands was underestimated for the current period condition. The areal extent of the upland herbland physiognomic type was above the HRV for All, BLM/FS, and Other land ownerships. In contrast, the areal extent of the upland shrubland physiognomic type was well below the HRV as a result of fire exclusion, excessive livestock grazing pressure, and the invasion of exotic forbs such as dyers woad, spotted knapweed, and leafy spurge.

The physiognomic type composition of the Snake Headwaters ERU riparian woodland PVG was similar for all ownership strata (table 3.98). The exotic herbland types were far outside the HRV since they did not exist historically. The exotic herbland component on both BLM/FS lands and Other lands was probably underestimated for the current period because of misidentification as native herbland types, which either existed alone, or as the understory of the shrubland and woodland types. The areal extent of the upland herbland physiognomic type was well below the HRV, especially on BLM/FS lands. This decline of the upland herbland type was caused by conversion to exotic vegetation, and successional development as a result of fire suppression. The areal extent of the early-seral riparian woodland physiognomic type was well below the HRV as a result of fire exclusion. Conversely, the areal extent of the mid-seral riparian woodland type was substantially above the HRV due to the development of early-seral stages into mid-seral stages, and the retrogression of late-seral riparian woodland into mid-seral stages. The areal extent of the late-seral riparian woodland physiognomic type was substantially below the HRV. This retrogression was caused by insect and disease mortality of the large overstory trees; harvest of overstory trees; and excessive livestock grazing pressure that eliminated understory reproduction of broadleaf trees.

The physiognomic type composition of the Snake Headwaters ERU dry forest PVG varied by ownership strata (tables 3.99 and 3.100). The upland herbland and upland shrubland physiognomic type areas were below the HRV on all ownership strata due to the decline of non-lethal fires that had maintained herb and shrub dominance. The amount of the early-seral forest physiognomic type was within the HRV for All ownerships. However, on BLM/FS lands, the area of the early-seral forest physiognomic type was above the HRV, whereas on Other lands, it was at the lower end of the HRV. The area of the mid-seral forest physiognomic type was very high relative to the HRV on all ownership strata. This was due to the retrogression of the late-seral multi-layer type into the mid-seral type as a result of mortality of the large, overstory trees from insects, disease, stress, and selective timber harvest practices. For all strata, the late-seral multi-layer type was quite low compared to the HRV, whereas the late-seral single-layer forest type was above or at the upper end of the HRV. The increased trend for late-seral single-layer physiognomic type development was the opposite of the trends observed for this type in every other ERU in the Basin. This unique trend may have

	Upland Herbland	59	23	46	45
	Upland Shrubland	7	78	54	55

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

been related to the mortality of understory tree species due to root rot diseases and spruce budworm, even in the absence of non-lethal fires that would have maintained single-layer structures. Fire exclusion eliminated the non-lethal and mixed fires that had maintained late-seral single- and multi-layer types, and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer types. In the peripheral areas that had been harvested, the larger shade-intolerant tree species had often been selectively cut. These were the trees that were more resistant to insect, disease, and stress mortalities.

In the dry forest PVG, the areal extent of the mid-seral forest types, dominated by shade-tolerant tree species, was well above the HRV (table 3.100). The conversion to dominance by shade-tolerant species was not as dramatic in the Snake Headwaters ERU as in many other ERUs because selective harvests of large, shade-intolerant trees had not been as extensive.

The physiognomic type composition of the cold forest PVG of the Snake Headwaters ERU also varied by ownership strata (tables 3.101 and 3.102). The areal extent of the early-seral physiognomic types was at the upper end of the HRV for the entire ERU and for BLM/FS lands. However, the areal extent of the early-seral type was well above the HRV for Other ownerships. The areal extent of the mid-seral forest physiognomic type occurred within the HRV for all ownership strata. The amount of the late-seral multi-layer forest physiognomic type was almost non-existent, while the amount of the single-layer physiognomic type was within HRV for all ownership strata. This general shift from late-seral to mid- and early-seral types appears to be related primarily to whitebark pine mortalities due to blister rust infestations combined with a lack of fire. Aspen (*Populus tremuloides*) was also in steep decline in the cold forest PVG in response to fire exclusion and excessive grazing pressure by livestock and native ungulates.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

Historically, aspen forest structures dominated much of the late-seral single-layer and mid-seral physiognomic types in the Snake Headwaters ERU.

The areal extent of the late-seral shade-tolerant forest physiognomic type were well below the HRV in the cold forest PVG (table 3.102). This followed the same general trend observed for the other forest types, including increased mid-seral types dominated by shade-tolerant species.

In response to the changes in regional and landscape conditions on forests, the primary changes in succession/disturbance regimes appears to have been a shift from moderate- and long-cycles, to a retrogressive-cycle regime. Most of the area within the wilderness and roadless areas has a low probability for the re-establishment of the native succession/disturbance regimes given the current limitations of prescribed fire use and the effects of blister rust on whitebark pine. The areas on the periphery of the Snake Headwaters ERU are in a similar state. There is a low probability of returning to the cycling, maintenance, and acceleration regimes of this system without restoration of landscape structures, fuel conditions, whitebark pine, and fire.

Southern Cascades ERU

The Southern Cascades ERU is located in north central Oregon (map 3.3). This ERU has very high relief (20 to 3,600 m) and a complex of low-elevation to high-elevation valleys, and steep mountains that developed primarily from glacial and erosional processes (map 3.17). Topography is generally steep and complex. Landforms include a mix of river valleys with breaks, and mountains and foothills with narrow valleys. Headwater and downstream watersheds are juxtaposed (map 3.21). Precipitation across the ERU is relatively high, averaging 92 centimeters per year, and has a steep gradient ranging from 36 centimeters at low elevations to 248 centimeters at high elevations. The diverse climate and topography support a high diversity of vegetation and dynamic disturbance regimes. The Southern Cascades ERU is primarily in ecoregion section M242C (map 3.1).

Climate is strongly influenced by oceanic storm patterns from the west and the rain-shadow effect of the Cascade Mountains. There is a very steep gradient from the deep snowpacks and high precipitation that occur on the Cascade crest, to little snow and the low precipitation of the Columbia River Gorge and its tributaries. Precipitation primarily falls in the form of winter snows, spring rains, and summer thunderstorms and showers. The upper elevations near the crest of the Cascades have a relatively low gradient from wet winter and spring conditions to moist-to-dry summer and fall conditions with a short growing season. Moving away from the Cascade crest, this changes rapidly to a very steep gradient from moist winter and spring conditions to very dry summer and fall conditions with a moderately-long growing season. The Southern Cascades ERU has very dynamic succession/disturbance regimes because of its inherent productivity, very-steep seasonal-moisture gradients, complex topography, and high carbon and moderate water stresses in upland areas.

There were substantial changes in fire regimes between the historical and current periods in the Southern Cascades ERU, primarily as a result of fire exclusion, timber harvest activities conducted at low and mid elevations, and livestock grazing practices (maps 3.22 and 3.23). Fire severity generally shifted from a mixture of non-lethal, mixed, and lethal regimes, to lethal in the forest PVGs due to the harvesting of the large, shade-intolerant and fire-, insect-, disease-, and stress-resistant species. Furthermore, the associated longer intervals between fires promoted the dominance of shade-tolerant species. These species are generally not as resistant to fires, insects, diseases, and stress factors.

From a regional-scale perspective, the Southern Cascades ERU is not highly susceptible to drought. Only the northeast portion of Deschutes County (that is, north of Bend and west of Redmond, Oregon) within this ERU receives less than 30 centimeters of precipitation annually (map 3.24). Currently, exotic plants are not prevalent in the Southern Cascades ERU, but diffuse knapweed is

present and expanding, particularly along roads. Approximately 23 percent of All lands and 21 percent of BLM/FS lands in this ERU are of high susceptibility to invasion by diffuse knapweed (table 3.47; map 3.37).

A moderate portion of public lands in the Southern Cascades ERU have had a history of livestock grazing (map 3.25). Many allotments were closed on public lands due to the decline of forage attributed to forest succession. Rangeland conditions on public lands have generally improved since the mid-1900s, except where exotic plants have become established in the dry PVGs. Riparian conditions have improved in some areas, but problems continue to persist in many areas with respect to stream-channel conditions and the lack of shrub and herbaceous cover.

Road densities in the Southern Cascades ERU are high throughout most of the area (map 3.28). However, landforms and soils generally have a low-to-moderate sensitivity to disruption of the hydrologic regimes (map 3.29). The Southern Cascades ERU landforms, geology, and soil development are generally not as susceptible to erosion and sediment transport as other mountainous ERUs. Where forested watersheds have been developed for timber harvest, road densities are commonly high. Because of the narrow valley bottoms and draws of the Southern Cascades ERU, many roads were developed in close proximity to streams. Consequently, these roads often constrict stream floodplain energy and have very short distances for sediment delivery.

The pattern of BLM/FS and Other land ownerships is moderately fragmented in the Southern Cascades ERU (map 3.30). There are some areas with relatively uniform BLM/FS ownership interspersed with areas of mixed and mosaic ownership patterns. A large portion of the BLM/FS lands has moderate and high risk of fire occurrence and associated high-intensity wildfires that could be difficult to suppress (map 3.31). These high-risk areas generally occur on the mid and lower elevations of the dry forest and moist forest PVGs.

At the landscape scale, there are some areas, particularly the break landforms, that also have high risk of fire. The moderate and high risks have been related primarily to potential wildfire occurrence from lightning and human-caused ignitions; dry spring, summer, and fall conditions; complex terrain; and heavy forest fuels that create the potential for severe fire behavior. The Southern Cascades ERU has a substantial area that has high fuel accumulations, high potential for crown fires, and high potential of forest insect-, disease-, and stress-related mortalities (map 3.32). These mortality agents more commonly occur in areas of dry forest and moist forest PVGs that have high NPP and high carbon stress. Past timber-harvest practices often removed most of the large, shade-intolerant trees that tend to be more resistant to these mortality agents. These large, shade-intolerant trees have generally been replaced by smaller, shade-tolerant tree species that are more susceptible to the above-mentioned mortality agents.

There are high and moderate risks related to the rural/wildland interface on the BLM/FS lands (map 3.33). At the landscape scale, the high-risk areas often occur at the edge of the break, foothill, or mountain landforms. Rural developments are typically associated with the adjacent narrow valley landforms that are on the edge of, or interspersed with, these landforms.

The composition of PVGs did not change substantially in the Southern Cascades ERU between the historical and current periods (table 3.103; maps 3.11 and 3.12). Six percent of the ERU was converted to the agricultural PVG at the expense of the dry shrub and cool shrub PVGs. Almost 4 percent of the ERU was converted to roads. The ERU was dominated by the moist, dry, and cold forest PVGs. A greater proportion of the cold forest PVG occurred on BLM/FS lands. PVG composition on Other ownerships was dominated by dry forest and moist forest PVGs. Approximately two-thirds of the road development occurred on BLM/FS lands.

Total[6]	57 / 101	59.2 / 100	43 / 101	44.7 / 98	100 / 100	103.9 / 102

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes.

Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

The physiognomic type composition of the dry forest PVG in the Southern Cascades ERU varied by ownership strata (tables 3.104 and 3.105). Exotic herbland physiognomic types were likely underestimated across all ownerships. Although the areal extent of the early-seral forest type occurred within the HRV for the entire ERU, it was above the range for BLM/FS lands, and just below the range for Other ownerships. These conflicting trends were likely due to the proportionately higher clearcutting and seed tree harvesting that had occurred on BLM/FS lands, and the greater proportion of selective and group harvest treatments on Other lands. The areal extent of the mid-seral forest physiognomic type on BLM/FS lands occurred within the HRV, whereas it was substantially above the HRV of Other lands. Most of the timber harvest activity on Other lands included the selective harvest of large, shade-intolerant trees from the late-seral types, which converted much of the type to mid-seral, whereas much of the timber harvesting on BLM/FS lands moved the late-seral to the early-seral types. The areal extent of the late-seral multi-layer forest physiognomic type occurred well above the HRV on BLM/FS lands, and well below the HRV on Other lands. In general, the late-seral type shifted to the mid-seral type because of fire exclusion, timber harvest activities, and insects, disease, and stress mortalities of overstory species. The areal extent of the late-seral single-layer physiognomic type was below the HRV for the ERU as a whole, at the lower end of the HRV on BLM/FS lands, and well below the HRV on Other lands. Again, the varying trends were due to much higher rates of selective cutting of the large, overstory trees on Other lands than on BLM/FS lands.

The formation of multiple canopy layers occurred much slower in the Southern Cascades ERU relative to adjacent ERUs. Consequently, much of the single-layer late-seral forest types remained in the single-layer stage for a longer time than in other ERUs, except for the Snake Headwaters and Upper Klamath ERUs, which had similar patterns. In areas where the forests were harvested using clearcut, seed tree, and planting treatments, forest succession was accelerated toward the mid-seral physiognomic types. Fire exclusion eliminated the non-lethal and mixed fire regimes that had maintained late-seral single- and multi-layer physiognomic types, and thinned shade-tolerant tree species in the early-, mid-, and late-seral multi-layer physiognomic types. This removed the trees that were more resistant to insects, disease, and stress mortalities.

The mid-seral forest physiognomic types, dominated by both shade-tolerant and shade-intolerant tree species, were at the upper limit of the HRV in the dry forest PVG of the Southern Cascades ERU (table 3.105). The areal extent of the late-seral single-layer shade-tolerant types was well above the HRV, whereas the areal extent of the late-seral multi-layer shade-tolerant types was at the upper limit of the HRV. Consequently, the dry forest PVG had high risks of substantial mortality from insects, disease, stress factors, and large, high-intensity fires.

In response to the changes in regional and landscape conditions, the succession/disturbance regimes went through a substantial shift from maintenance and acceleration regimes, to cycling and retrogression regimes. Most of the areas have been roaded and have changed from maintenance to cycling regimes via timber harvest activities and fire exclusion. There is a low probability of restoring native succession/disturbance regimes without simultaneous restoration of the stand structures and fuel conditions.

The physiognomic type composition of the Southern Cascades ERU moist forest PVG varied by ownership strata (table 3.106 and 3.107). The areal extent of the early-seral forest physiognomic type was within the HRV on BLM/FS lands, but well below the HRV on Other ownerships. This difference was likely attributable to fewer clearcut and seed tree timber harvests on Other lands relative to BLM/FS lands. The areal extent of the mid-seral physiognomic type also varied by ownership; it was well below the HRV on BLM/FS lands, but well above the HRV on Other lands. Again, it appears that most of the harvests on

	Late-seral Single-layer Forest	29	24	12	9
	Mid-seral Forest	37	43	39	34

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

Other lands were selective cuts of the large, overstory trees of the late-seral types, which converted these types to mid-seral or late-seral single-layer types. The late-seral multi- and single-layer forest physiognomic types changed in a like manner, regardless of ownership strata. The areal extent of the late-seral multi-layer physiognomic type was at the lower limit of the HRV, while the late-seral single-layer physiognomic type was above the upper areal extent of the HRV. In areas where the forests were cycled using clearcut and seed tree treatments, forest succession was accelerated toward the mid-seral physiognomic type through the use of advanced regeneration plantings.

Fire exclusion eliminated the non-lethal and mixed fire regimes that had maintained late-seral single- and multi-layer physiognomic types, and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer physiognomic types. This removed the trees that were more resistant to insects, disease, and stress mortalities. Clearcut, seed tree, shelterwood, and group-selection timber-harvest activities created a mosaic of early-seral patches containing few live or dead-standing tree structures, and high down-fuel accumulations. In the matrix areas surrounding these patches, the large trees and dead-standing trees were often selectively harvested. This combination of factors homogenized landscape patterns and increased the risks of fire-, insect-, disease-, and stress-related mortality.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

In the current period, the amount of shade-tolerant species in the moist forest PVG of the Southern Cascades ERU appears to have been very high in the late-seral single-layer physiognomic type relative to the HRV, regardless of ownership strata (table 3.107). This suggests that the timber harvests that converted forests from multi-layer to single-layer types, or that maintained single-layer structures, selected against the shade-intolerant species. The areal extent of the shade-tolerant species for the mid-seral types were within the HRV for the entire ERU, within the HRV on BLM/FS lands, but above the HRV on Other land ownerships. Consequently, risks of substantial mortality from insects, disease, stress, and large high-intensity fires, were higher on Other lands.

With the exception of the late-seral multi-layer physiognomic type, the changes to the Southern Cascades ERU cold forest PVG physiognomic type compositions were similar among ownership strata (tables 3.108 and 3.109). The observed increase in the areal extent of the early-seral physiognomic type was likely due to recent clearcut and seed-tree harvest activities in systems that had mixed or maintenance regimes, as well as to the loss of whitebark pine to blister rust. The observed decrease in the areal extent of the mid-seral physiognomic type was a consequence of succession to late-seral multi-layer forest type in relation to fire exclusion. The areal extent of the late-seral multi-layer forest types were substantially above the HRV of the ERU and BLM/FS lands, but within the HRV of Other ownerships. The late-seral single-layer physiognomic type was essentially non-existent for all ownership strata. Fire exclusion eliminated the non-lethal and mixed fire regimes that had maintained late-seral single- and multi-layer physiognomic types, and thinned shade-tolerant tree species in the early-, mid-, and late-seral multi-layer physiognomic types. These were the trees that were more resistant to insects, disease, and stress mortalities.

Shade-intolerant species increased in the cold forest PVG of the Southern Cascades ERU, increased in comparison to the HRV in the early-seral and late-seral multi-layer physiognomic types, and decreased in comparison to the HRV in the mid-seral physiognomic type (table 3.109). Although the amounts of shade-intolerant species in the late-seral single-layer physiognomic type were almost non-existent, they were also very low in the HRV. The observed trends were similar, regardless of ownership strata. The increase of shade-intolerant species in the early-seral type appears to be a response to artificial planting of harvest units, while the increase in the late-seral type may be a relative increase as a result of insect- and pathogen-caused mortality of shade-tolerant species.

In response to the changes in regional and landscape conditions, the succession/disturbance regimes went through a substantial shift from a mix of moderate-cycle and maintenance regimes, to a mix of long-cycle and retrogressive-cycle regimes. There is a low probability of restoring native succession/disturbance regimes without restoring native landscape structures and fuel conditions. Trends for the cool shrub PVG are displayed in table 3.109a.

Upper Clark Fork ERU

The Upper Clark Fork ERU is located in western Montana (map 3.3). This ERU has moderately high relief (1,000 to 3,200 m) with a complex of wide valleys, foothills, and mountains (map 3.17). Topography is complex as a result of erosional processes and mountain glaciation. Landforms include a complex mix of wide valleys, foothills, mountains, and narrow valleys with a mix of headwater and downstream watersheds (map 3.21). The ERU is primarily in ecoregion section M332B (map 3.1).

Precipitation throughout the Upper Clark Fork ERU averages 73 centimeters per year with a range from 36 to 163 centimeters. The steep precipitation gradient in conjunction with the complex topography results in very diverse vegetation. Climate is strongly influenced by both oceanic storms from the west as well as the continental climates from the east. The area is strongly affected

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

by the rain-shadow effect of the Bitterroot Mountains to the west. Precipitation primarily falls in the form of winter snows, spring rains, and summer thundershowers. There is a moderate gradient from relatively moist spring conditions, to dry summer and fall conditions with a fairly long growing season. The Upper Clark Fork ERU has relatively high biogeochemical energy dynamics, moderately high rates of inherent NPP and nutrient cycling, and moderate carbon stress and low water stress in upland areas.

There were substantial changes in fire regimes in the Upper Clark Fork ERU primarily as a result of fire exclusion (maps 3.22 and 3.23). Fire severity generally shifted from non-lethal and mixed, to lethal regimes in the forest PVGs, due to fire suppression and longer intervals between fires. Severity did not change substantially, but intervals between fires increased in the non-forest PVGs due to fire exclusion, removal of fine fuels by livestock grazing, and encroachment of conifers.

From a regional perspective, the Upper Clark Fork ERU does not have a substantial area with high risk of drought; only a small portion of the ERU receives less than 30 centimeters annual precipitation (map 3.24). Consequently, the dry forest PVG and most of the non-forest PVGs that were altered by the invasion of exotic plants or from excessive livestock grazing pressure have a fairly high potential for restoration. However, at the landscape scale, the foothill landforms have a high proportion of steep, south-facing topographic settings and tend to be droughty environments.

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

There has been a long history of livestock grazing on the public lands of the Upper Clark Fork ERU (map 3.25). Much of the land area in public ownership has been grazed by sheep and cattle since the late-1800s. Substantial improvements in rangeland conditions and associated watershed conditions have occurred since the mid-1900s. However, many of the high-elevation sheep allotments that were subjected to excessive grazing pressure, and that experienced soil-cover loss and extensive erosion, have been very slow to recover. Even though many of these high-elevation allotments were closed or experienced stocking-rate reductions, there are areas that have not recovered vegetation cover.

The dry forest and dry grass PVGs in the Upper Clark Fork ERU have been particularly susceptible to exotic plant invasions, especially the perennial forbs: spotted knapweed, leafy spurge, and sulfur cinquefoil. Approximately 39 and 13 percent of All lands, and 19 and 2 percent of BLM/FS lands in this ERU are of high susceptibility to invasion by spotted knapweed and leafy spurge, respectively (table 3.47; maps 3.35 and 3.36). Currently, rangeland riparian areas are also in a somewhat degraded condition, but are recovering relatively quickly because of the recent emphasis on riparian management on BLM/FS lands.

Road densities in the Upper Clark Fork ERU are mostly moderate and high, with some areas of low and very-low densities, and a few areas without roads (map 3.28). Much of this ERU has sensitive watersheds because of its steep topography and highly-erosive granitic or metasedimentary soils. Some of the watersheds are in degraded conditions due to the moderate and high road densities on sensitive watersheds (map 3.29).

The pattern of BLM/FS and Other land ownerships is highly fragmented in the Upper Clark Fork ERU (map 3.30). Most of the area is in mixed or mosaic BLM/FS ownership with a few areas having uniform patterns. Much of the BLM/FS land has moderate risks of fire occurrence and associated high-intensity wildfires that could be difficult to suppress (map 3.31). At the landscape scale, there are areas of high fire risks. The moderate- and high-risk areas have been attributed to wildfire occurrence from lightning ignition, dry summer and fall conditions, dissected and steep terrain, and a mosaic of woody and grass fuels. The Upper Clark Fork ERU also has a moderate component of areas with high fuel accumulations, high potential for crown fire, and high forest insect-, disease-, and stress-related mortalities (map 3.32). The high-risk areas are predominantly dry forests that have high carbon stress. Past timber harvests often removed most of the large, shade-intolerant trees that were more resistant to these types of mortalities. The large shade-intolerant trees have generally been replaced by smaller, shade-tolerant tree species that are more susceptible to the above-mentioned mortality agents.

There are moderate- and high-risk areas of rural/wildland interface on the BLM/FS lands in the Upper Clark Fork ERU (map 3.33). At the landscape scale, the high-risk areas often occur at the edge of the foothill environments. Rural developments are typically associated with the wide valley, bench, or narrow valley landforms that are on the edge of, or interspersed with, the steeper, complex topography of the foothill landforms. The foothill landforms typically occur on the BLM/FS lands.

Between the historical and current periods, PVG composition did not change substantially in the Upper Clark Fork ERU (table 3.110, maps 3.11 and 3.12). Approximately 9 percent of the area was developed for agricultural and urban uses at the expense of the dry grass and cool shrub PVGs. Another 2.8 percent of the ERU was converted to roads. The majority (61%) of roads are located on Other land ownerships. The cold, dry, and moist forest PVGs dominated the ERU as a whole. The cold forest PVG dominated BLM/FS lands, whereas the dry forest PVG dominated Other lands.

Changes in the physiognomic type composition of the dry forest PVG were similar for all ownership strata in the Upper Clark Fork ERU (tables 3.111 and 3.112). The amount of exotic herbland was substantially underestimated because of forest overstory cover.

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes.

Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

[3]+ = < 0.5%.

The areal extent of the mid-seral forest physiognomic type was almost three times the HRV across all ownership strata due to the shift of the late-seral forest types to the mid-seral types. This was caused by the selective harvesting of large, overstory trees and tree mortalities related to stress, insects, and diseases. The shift was also partly due to the succession of the early-seral types into the mid-seral types. Current period late-seral multi- and single-layer physiognomic types were essentially non-existent in all ownership strata. The late-seral multi- and single-layer forest types had shifted primarily to mid-seral types because of the selective harvest of large overstory trees; insect, disease, and stress mortalities associated with overstory trees; and the growth of shade-tolerant species in the understory. The cause for the stress-, insect-, and disease-related mortalities was the change to higher-density stocking levels of the more susceptible, shade-tolerant tree species.

Fire exclusion in the Upper Clark Fork ERU eliminated the non-lethal and mixed fires that had maintained late-seral single- and multi-layer physiognomic types, and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer physiognomic types. The larger shade-intolerant tree species were often selectively harvested. These trees were more resistant to insect, disease, and stress mortalities. Clearcutting and seed-tree timber-harvest activities commonly created small early-seral patches containing few live or dead-standing trees, and higher down-fuel accumulations. These factors, in conjunction with a climatic trend commencing in the 1980s that appears to have resulted in drier spring, summer, and fall periods, increased the risks of wildfire.

The current period composition of the dry forest PVG in the Upper Clark Fork ERU was dominated by mid-seral physiognomic types, regardless of ownership strata (table 3.112). The ERU was so strongly dominated by the mid-seral physiognomic type that the mid-seral types composed of both shade-tolerant and shade-intolerant species exceeded their HRV.

The historical to current period change in physiognomic type composition of the Upper Clark Fork ERU moist forest PVG was similar across all land ownership strata (tables 3.113 and 3.114). The areal extent of the early-seral forest physiognomic type was below the HRV due to fire exclusion, a lack of cycling treatments that mimic lethal fire regimes, and the decreased duration of the early-seral stage attributed to tree planting and the promotion of rapid regeneration. The areal extent of the mid-seral forest physiognomic type was nearly double the HRV as a consequence of early-seral forest succession into, and the retrogression of late-seral forests into mid-seral forests. The late-seral multi- and single-layer forest types were essentially eliminated in the Upper Clark Fork ERU in response to the harvesting of large, overstory trees. The non-lethal and mixed fire regimes that had maintained, accelerated, and cycled late-seral and mid-seral forest types had substantially declined since the historical period. Harvesting of the large, shade-intolerant, overstory trees left smaller trees as the dominant layer, but did not promote their growth to dominance.

With the exception of the mid-seral type, the areal extent of the moist forest physiognomic types composed of shade-intolerant species were below their HRV, regardless of ownership strata. With respect to the mid-seral types, those dominated by shade-intolerant species exceeded the HRV, as did those dominated by shade-tolerant species. As with the dry forest PVG, the current distribution of physiognomic types was so strongly skewed toward the mid-seral types that both shade-tolerant and shade-intolerant mid-seral types exceeded their respective HRV (table 3.114).

We detected different trends in physiognomic type composition of the cold forest PVG among the ownership strata (tables 3.115 and 3.116). The areal extent of the early-seral forest physiognomic type was substantially below the HRV for the entire Upper Clark Fork ERU, as well as for BLM/FS lands. However, the areal extent of the early-seral type on Other land ownerships fell within the HRV range. There was such a small amount of

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

this PVG on Other lands that it was difficult to speculate why the trends were not similar. For BLM/FS lands, the primary factor of change was succession of the early-seral into the mid-seral type. The areal extent of the mid-seral forest physiognomic type was almost double the HRV, whereas the late-seral multi- and single-layer forest physiognomic types were essentially non-existent. The large increase in the areal extent of mid-seral types and decrease in the areal extent of late-seral types was attributed to the succession of early-seral to mid-seral, and the retrogression of late-seral to mid-seral. In general, there had been little timber harvest activity within the cold forest PVG of this ERU. Most changes were likely related to fire exclusion, bark beetle attacks, blister rust, and succession.

The relationship between the cold forest physiognomic types, dominated by shade-tolerant or shade-intolerant species, mirrored those of the dry forest and moist forest PVGs in the Upper Clark Fork ERU (table 3.116). That is, the areal extent of the late-seral and early-seral forest types composed by shade-intolerant species in the current period were below the HRV, whereas the mid-seral shade-intolerant forest type occurred above its HRV (as did the mid-seral shade-tolerant forest type). The trend generally indicates that the shade-intolerant whitebark pine was declining due to fire exclusion and mortality from blister rust, and was being replaced by subalpine fir. Subalpine larch was also declining as a result of fire exclusion, and was being replaced by subalpine fir.

however, some errors may remain.

There was an increase in the mid-seral type because of succession from the early-seral type and retrogression from the late-seral type. We suspect that the shade-intolerant species remained strong because of lodgepole pine predominance in the mid-seral stages of these warmer and moister cold forest PVGs of the Upper Clark Fork ERU.

In response to the changes in regional and landscape conditions on the Upper Clark Fork ERU forest and rangelands, the primary change in succession/disturbance regimes appears to have been a shift from a mix of moderate and accelerated cycles, to a mix of long and retrogressive cycles. There is a low probability of restoring native succession/disturbance regimes without a concurrent restoration of landscape structures, fuel conditions, whitebark pine, and fire.

Upper Klamath ERU

The Upper Klamath ERU is located in south central Oregon (map 3.3). This ERU has moderate relief (900 to 2,600 m) with a complex of wide, low-elevation valleys interspersed with foothills and mountains (map 3.17). Topography is moderately complex. Landforms include a mix of river valleys with breaks, foothills, and mountains. Watersheds are mixed between downstream and headwater systems (map 3.21). Precipitation is moderate (averaging 59 centimeters per year) and has a moderate gradient ranging from 39 centimeters at lower elevations, to 105 centimeters at higher elevations. The overall diversity of vegetation is low. The Upper Klamath ERU is primarily in ecoregion section M261G and M242C (map 3.1).

Climate is strongly influenced by the oceanic storm patterns from the west. The rain-shadow effect in the Upper Klamath ERU is less than for the Northern Cascades and Southern Cascades ERUs because of lower crest elevations. However, the influence of the Pacific Coast range is substantial at this latitude, creating a rain shadow that affects both the westside and eastside of the Cascade Mountains. Precipitation primarily falls as winter snows, spring rains, and summer thunderstorms and showers. There is a very steep seasonal gradient from moist winter and spring conditions, to very dry summer and fall conditions with a moderately-long growing season. The Upper Klamath ERU has very dynamic succession/disturbance regimes because of moderate inherent productivity, very-steep seasonal-moisture gradients, complex topography, and the associated high carbon and high water stress on upland areas.

There were substantial changes in fire regimes between the historic and current periods, primarily as a result of fire exclusion and past timber harvest activities (maps 3.22 and 3.23). In the Upper Klamath ERU forest PVGs, fire severity generally shifted from a mixture of non-lethal, mixed, and lethal regimes, to predominantly a lethal regime. Changed fire regimes resulted from harvesting of large, shade-intolerant, and fire-, insect-, disease-, and stress-resistant tree species, as well as longer fire-intervals that allowed successional dominance by shade-tolerant species. These shade-tolerant species were generally less resistant to fire, insect, disease, and stress.

In the non-forest PVGs, some areas have experienced invasions by exotic annuals including grasses, cheatgrass, and medusahead. If exotic communities are not grazed, they become highly flammable. If they are grazed, fine-fuels are reduced and fire intervals are extended. In general, the fire regime of the non-forest PVGs of the Upper Klamath ERU shifted from non-lethal to lethal. There was an associated increase in the variability of fire interval length in these areas, which was attributed to differing levels of grazing pressure.

The Upper Klamath ERU has a negligible amount of area that receives less than 30 centimeters of annual precipitation (map 3.24). However, drought is relatively frequent in this ERU. During the period from 1895 to 1994, drought was documented 18 percent of the time (table 3.38; climate division: Oregon South Central). This level of drought frequency, in conjunction with the relatively infrequent periods of above-normal precipitation for two or more years in succession (only 7 such periods were documented during the 1895-1994

period, table 3.38), confirmed that this ERU has a high-risk, droughty environment. Such an environment reduces success rates of restoration in non-forest PVGs that have been altered by the invasion of exotics or by excessive livestock grazing pressure.

Cheatgrass, medusahead, and yellow starthistle are prevalent exotic plants in the Upper Klamath ERU. The dry forest and dry grass PVGs are notably susceptible to invasion by these species. Approximately 28 and 7 percent of All lands, and 26 and 1 percent of BLM/FS lands in the Upper Klamath ERU are of high susceptibility to invasion by cheatgrass and yellow starthistle, respectively (table 3.47; maps 3.26 and 3.27). Distribution of medusahead within this ERU has been associated greatly with soils that shrink or swell from drying or wetting (table 3.46; map 3.19).

A moderate portion of this ERU has had a history of livestock grazing on public lands (map 3.25). Rangeland conditions on public lands have generally improved since the mid-1900s, except where exotics have invaded the dry PVGs. In some areas, current riparian conditions have improved, but problems continue to persist in many areas relative to stream-channel conditions, and the lack of shrub and herbaceous cover.

Road densities throughout most of the Upper Klamath ERU are high (map 3.28). However, landforms and soils in this ERU generally have a low to moderate sensitivity to the disruption of hydrologic regimes (map 3.29). The types of landforms, geology, and soil development found in this ERU are generally not as susceptible to erosion and sediment transport as those in other mountainous ERUs. Where forested watersheds have been developed for timber harvest, road densities are commonly high.

The pattern of BLM/FS and Other land ownerships is highly fragmented in the Upper Klamath ERU (map 3.30). Few areas have a uniform distribution of BLM/FS lands; most areas have mixed and mosaic BLM/FS ownership patterns. Most of the BLM/FS lands have moderate and high risks of fire occurrence and associated high-intensity wildfires that could be difficult to suppress (map 3.31). High-risk areas generally occur on lower-elevation dry forests. At the landscape scale, there are some areas, particularly the break landforms, that also have high fire risk. The moderate and high risks are related primarily to potential wildfire occurrence from lightning and human-caused ignition; very dry summer and fall conditions; complex terrain; and heavy forest fuels that create the potential for severe fire behavior.

A substantial portion of the Upper Klamath ERU has high fuel accumulations, high potential for crown fires, and high risks of forest insect-, disease-, and stress-related mortalities (map 3.32). These high-risk areas have been associated with the dry forest and moist forest PVGs, which have high NPP, high carbon stress, and high water stress. Past timber harvest practices often removed many of the large, shade-intolerant trees that were more resistant to these mortality agents. These large, shade-intolerant trees have been generally replaced by large and small shade-tolerant tree species that are more susceptible to the above-mentioned mortality agents.

There are high and moderate risks related to the rural/wildland interface on the BLM/FS lands (map 3.33). At the landscape scale, the high-risk areas often occur at the edge of the break and foothill landforms. Rural developments are typically associated with the adjacent valley landforms that are on the edge of, or interspersed with, these landforms.

PVG composition did not change substantially from the historical to the current period in the Upper Klamath ERU (table 3.117; maps 3.11 and 3.12). Seven percent of the ERU was converted to the agricultural PVG, which was derived primarily from the dry grass PVG. The dry forest PVG dominated the ERU. Composition of PVGs on BLM/FS lands followed the same pattern, but with a slightly higher proportion of moist forest

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes. Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

and cold forest PVGs than on Other lands. PVG composition on Other ownerships was dominated by the dry forest PVG, with small amounts of the dry grass, dry shrub, and cool shrub PVGs. Approximately 3.8 percent of the total area was converted to roads, and nearly evenly distributed between BLM/FS lands and Other ownerships.

The physiognomic type composition of the Upper Klamath ERU dry forest PVG changed in a similar manner among ownership strata (tables 3.118 and 3.119). Exotic herblands were underestimated across all ownerships. The areal extent of the early-seral forest physiognomic type was at the lower end of the HRV due to recent clearcut and seed-tree harvest activities. The areal extent of the mid-seral forest physiognomic type was below the HRV for all strata, due to the succession of mid-seral to late-seral types. The amount of the late-seral multi-layer forest physiognomic type was substantially above the HRV, whereas, the amount of the late-seral single-layer physiognomic type occurred within the HRV for all strata. There was a general shift from the late-seral single-layer to the late-seral multi-layer type, and from the mid-seral to the late-seral multi-layer type as a result of fire exclusion and selective harvesting of large, shade-intolerant trees. In areas where the forests were harvested by clearcut and seed-tree treatments, forest succession was accelerated toward the mid-seral physiognomic types through the use of planting and other silvicultural techniques that promote rapid regeneration.

Fire exclusion in the Upper Klamath ERU eliminated the non-lethal and mixed fire regimes that had maintained late-seral single- and multi-layer physiognomic types, and thinned shade-tolerant tree species in early-, mid-, and late-seral multi-layer structures. These were the trees that were more resistant to insect, disease, and stress mortality. Clearcut, seed-tree, shelterwood, and group-selection timber-harvest activities commonly created a mosaic of early-seral patches with few live or dead-standing trees, and higher down-fuel accumulations. In the matrix areas surrounding the patches, the large trees and dead-standing trees were often selectively harvested. This combination of factors homogenized landscape patterns and increased the risks of fire, insect, disease, and stress mortalities.

In the dry forest PVG of the Upper Klamath ERU, the areal extents of the mid-seral and late-seral physiognomic types composed by shade-tolerant species were below their HRV for the ERU as a whole (table 3.119). Conversely, the area of the late-seral shade-intolerant multi-layer forest physiognomic type exceeded its HRV. With the exception of the mid-seral shade-intolerant physiognomic type, these trends were similar for BLM/FS lands within the Upper Klamath ERU. Tree mortality risks associated with fire, insects, disease, and stress seem particularly problematic within the late-seral shade-tolerant physiognomic types, both of which substantially exceeded their HRV.

From the historical to the current period, physiognomic type composition of the moist forest PVG in the Upper Klamath ERU varied between ownership strata (tables 3.120 and 3.121). The areal extent of the early-seral forest physiognomic type was within the HRV for All and BLM/FS ownership strata, whereas it was well above the HRV for Other ownerships. These trends were likely because of the extensive even-age timber harvesting (that is, clearcuts or seed-tree cuts) and wildfire that occurred on Other lands. The areal extent of the mid-seral forest physiognomic type was below the HRV of all ownership strata due to its succession to the late-seral multi-layer physiognomic type. The amount of the late-seral single- and multi-layer forest types was well above the HRV for all ownership strata. This was most likely the result of extensive selective timber harvesting of large, shade-intolerant trees, which allowed the development of forests comprised mainly of mid-seral shade-tolerant species.

Mid-seral forests, dominated by shade-tolerant tree species, were generally not present in the Upper Klamath ERU. This reflected the overall decline of the mid-seral physiognomic types. The late-seral shade-tolerant composition for both the multi- and single-layer physiognomic types was well

above the HRV as a result of the selective harvesting of shade-intolerant trees, fire exclusion, and succession. These past disturbances and successional regimes increased the susceptibility of the moist forest PVG to mortality from stress, insects, disease, and fire.

In response to the changes in regional and landscape conditions, the succession/disturbance regimes in the Upper Klamath ERU went through a substantial shift from a mix of maintenance and long-cycle regimes, to a mix of short-cycle and retrogressive-cycle regimes. Most of the areas are roaded and have been altered by timber harvest and fire exclusion. Restoration of native succession/disturbance regimes can only be accomplished by a concurrent modification of vegetation structure and composition, and fuel conditions.

Upper Snake ERU

The Upper Snake ERU is located primarily in southern Idaho (map 3.3). This ERU has relatively low relief (1,200 to 3,000 m) with a complex of valleys and plains with interspersed breaks, scattered foothills, and mountains (map 3.17). Topography is generally gentle to rugged due to different types of fluvial, volcanic, and erosional processes. Landforms include a mix of plains, valleys, breaks, foothills, and mountain ranges, with a mix of headwater and mainstem watersheds (map 3.21). The ERU is primarily in ecoregion sections 342B and 342D (map 3.1).

Precipitation averages 27 centimeters per year and ranges from 18 to 60 centimeters. However, precipitation on most sites is within 5 centimeters

[1]Land Ownership Group: BLM/FS lands = BLM- and FS-administered lands; Other lands = all land other than BLM- and FS-administered lands; All lands = BLM/FS lands + Other lands.

[2]Current year = circa 1991; Historical year 0 = circa 1850 to 1900 (initiated model simulation); Historical year 50 = simulation output at year 50; Historical year 100 = simulation output at year 100.

[3]+ = < 0.5%.

of the average. Areas on the low end of the annual-precipitation range are generally confined to the desert and break areas; areas at the upper end of the range are confined to the mountain areas.

Climate is influenced by a mix of weather patterns. The Upper Snake ERU is influenced by the rain-shadow effect of the Cascade Mountains to the west, strongly affected by the intermountain storm patterns from the southwest, and influenced by the continental weather patterns from the east. Precipitation falls as winter rains or snows, spring rains, and summer thunderstorms and showers. Winds are common and when combined with relatively high growing-season temperatures cause high rates of evapotranspiration and soil surface desiccation. There is a moderately-steep moisture gradient from somewhat moist winter and spring conditions, to dry summer and fall conditions with a long growing season. Soils are quite complex due to variation in parent material, effects of periglacial processes, depth, salinity, clay accumulation, and presence of impermeable subsurface layers. The number of plant species able to dominate in this type of environment is relatively low. Consequently, vegetation diversity is fairly low. Net primary productivity is low, nutrient cycling is moderate, carbon stress is low, and water stress is high.

There have been substantial changes in fire regimes of the Upper Snake ERU between the historical and current periods, primarily as a result of fire exclusion, excessive livestock grazing pressure, and the invasion of exotic annual grasses (particularly cheatgrass)(maps 3.22 and 3.23). In the non-forest PVGs, cheatgrass is prevalent, particularly in the northwest portion of the ERU (Pellant and Hall 1994). If these cheatgrass-invaded areas had not been grazed in the past, they became highly flammable. If the areas had been grazed however, fine-fuel production was reduced, and fire-return intervals extended. However, for the most part, fire frequency has declined in these cheatgrass-invaded areas of the Upper Snake ERU (map 3.23). In contrast to other ERUs that have more moisture, greater forest vegetation cover, and high fire occurrence in drought years, the Upper Snake ERU has typically experienced fires in the moister years that have produced higher amounts of fine-grass fuels.

From a regional-scale perspective, the Upper Snake ERU has substantial area that receives less than 30 centimeters of precipitation annually (map 3.24). Compared with the Owyhee Uplands ERU to the west however, drought years in the Upper Snake ERU have been documented less frequently (only 15% of the time from 1895-1994; table 3.38, climate division: Idaho Upper Snake River Plains). As a consequence, the potential for restoration activities in the non-forest PVGs in the Upper Snake ERU is higher relative to more westerly ERUs, particularly for non-forest PVGs that have been altered by excessive livestock grazing pressure or the invasion of exotics.

The Upper Snake ERU has had a long history of livestock grazing on both its private and public lands (map 3.25). Much of the public land-ownership area in grazing allotments has been grazed by livestock since the late-1800s. Currently, most rangeland riparian areas are in degraded conditions. Stream and river banks have typically been downcut to the point where they have no associated riparian area. By the mid-1900s however, some improvements in rangeland conditions and associated watershed condition had become apparent.

In the last 100 years, the invasion and spread of exotic plants has been noteworthy. Cheatgrass, dyers woad, leafy spurge, spotted knapweed, and Russian knapweed have become prevalent in portions of the Upper Snake ERU. Across All ownerships, areas of high susceptibility to invasion by cheatgrass, leafy spurge, and spotted knapweed compose 46, 39, and 25 percent of the ERU, respectively (table 3.47; maps 3.26, 3.35, and 3.36). Approximately 75, 6, and 9 percent of BLM/FS lands are of high susceptibility to invasion by cheatgrass, leafy spurge, and spotted knapweed, respectively (table 3.47; maps 3.26, 3.35, and 3.36).

Native biodiversity declined in the Upper Snake ERU between the historical and current periods because of exotic plant invasions, particularly in the dry shrub PVG (table 3.122). However, native plant communities that do not have a major exotic component currently persist in this ERU, for example on the Idaho National Engineering Laboratory land. These native plant communities are typically located in historically inaccessible areas, or in areas without water or water developments, and have had little to no history of excessive livestock grazing pressure. However, there are extensive areas that are characterized as saline soils, or susceptible to erosion by water and wind (table 3.46; maps 3.18, 3.34, 3.38, 3.39, 3.40, 3.41, 3.42, 3.43, and 3.44).

Road densities in the Upper Snake ERU are generally moderate to high, with some areas having low and very-low densities (map 3.28). Landforms and soils in this ERU generally are not sensitive to hydrologic regime disruption attributable to steep topography or high density of roads (map 3.29).

The pattern of BLM/FS and Other land ownerships is relatively fragmented; only a moderate proportion of the Upper Snake ERU is under BLM/FS ownership (map 3.30). Most of the breaks, plains, foothills, and mountains occur as a mosaic of BLM/FS ownership, and mixed or Other ownership patterns occur in valley areas.

Approximately 35 percent of the BLM/FS lands has moderate risks of fire occurrence and the associated high-intensity wildfires that could be difficult to suppress (map 3.31). These fire risk areas generally occur in the dry shrub PVG. At the landscape scale, there are some areas, particularly the break landforms, that have high fire risks. The moderate and high risks have been related primarily to potential wildfire occurrence from lightning or human-caused ignition; dry spring, summer, and fall conditions; complex break or foothill terrain; and flammable annual grass fuels intermingled with dry shrublands that create the potential for severe fire behavior. The Upper Snake ERU has very few areas with high fuel accumulations, high potential for crown fire, and high potential of forest insect, disease, and stress-related mortalities (map 3.32).

There are moderate risks related to the rural/wildland interface on the BLM/FS lands in the mixed and mosaic ownership patterns (map 3.33). At the landscape scale, there are some high-risk areas adjacent to small rural developments. Rural developments are typically associated with the adjacent valley and plains landforms that are on the edge of, or interspersed with, the steep and complex topography of the break landforms. The break landforms are typically located on BLM/FS lands or other public lands.

Between the historical and current periods, PVG composition changed substantially in the Upper Snake ERU due to agricultural development (table 3.122; maps 3.11 and 3.12). Thirty-six percent of the ERU was developed for agriculture at the expense of the dry shrub PVG. The dry shrub PVG dominated all ownership strata. Approximately 2.4 percent of the total area was converted to roads, of which 0.7 percent was on BLM/FS lands and 1.6 percent was on Other lands.

Trends in physiognomic type composition of the dry shrub PVG were similar across all ownership strata (table 3.123). Exotic herblands were a substantial component of the current period dry shrub PVG. The exotic herbland component on both BLM/FS and Other lands was probably underestimated for the current period because of misidentification as the upland herbland physiognomic type, which either existed alone or as the understory of the upland shrubland physiognomic type. Exotic plants may have dominated as much as 70 percent of the upland herbland physiognomic type and were a common component in much of the upland shrubland physiognomic type. The native system was dominated by a shifting mosaic of upland herbland and upland shrubland physiognomic types that was maintained by frequent non-lethal and mixed fires. As a result of the invasion of exotic forbs and annual grasses, excessive livestock grazing pressure, and fire exclusion, this shifting mosaic was generally replaced by a relatively static mosaic of patches of exotic forbs

[1]Land Ownership Group: BLM/FS = BLM- and FS-administered lands; Other = all land other than BLM- and FS-administered lands; All = BLM/FS lands + Other lands.

[2]The PVG percentage for All land ownership group = each PVG percentage for BLM/FS land ownership group + the PVG percentage for Other land ownership group. The totals for All land ownership will exceed 100 percent because the area in roads was not subtracted from PVG categories.

[3]ERU = relative percent of ERU area that the PVG (under that specific ownership and time period) contributes.

Ownership = relative percent of the entire ownership within the ERU that the PVG (under that specific ownership and time period) contributes. For example, given: "BLM/FS, Historical, PVG X, 10 / 20"; ERU would indicate that during the historical period, 10 percent of the ERU area was made up of PVG X on BLM/FS ownership. Given the same example, Ownership would indicate that during the historical period, PVG X on BLM/FS ownership contributes 20 percent to the BLM/FS lands.

[4]+ = < 0.5%.

[5]NA = Not Applicable.

[6]Total percent may not equal 100 due to rounding.

Map 3.44—Susceptibility of rangeland health to management-induced disturbance stresses in the Basin as indicated by the linking of climate with soil salinity and soil sodicity. Shaded areas represent soil map units with a 75 percent or greater areal extent of soils having these specific soil-property indicators: salinity of 8 to 16 millimhos per centimeter (mmhos/cm), and a SAR between 5 to 12; none of the other three, focal, soil-property indicators are present in the soils over 75 percent of their extent. Soil map units existing in the less-than-25-centimeters precipitation zone represent rangeland health of high susceptibility to management-induced disturbance stresses; soil map units existing in the 25-to-30-centimeters precipitation zone represent rangeland health of moderate susceptibility; and soil map units existing in the greater-than-30-centimeters precipitation zone represent rangeland health of moderate-low susceptibility.

[3]+ = < 0.5%.

and annual grasses, patches of shrub/annual grasses, and a few remnant patches of native upland shrub/bunchgrass.

In response to the changes in regional and landscape conditions on rangelands, the succession/disturbance regimes went through a substantial shift from a mixture of moderate- and long-cycle regimes to a mix of retrogressive- and short-cycle regimes, primarily in response to the invasion of exotic species, extensive livestock grazing, and fire exclusion. Given the lack of technology related to long-term rehabilitation of areas invaded by exotic species, there is little chance of restoring native succession/disturbance regimes. A higher likelihood of restoration opportunities occurs in the more productive environments. Riparian environments have high potential for restoration given stabilization of their hydrologic regimes. Trends for the cool shrub PVG are displayed in a table in appendix 3-N.

Regional Relationships of Biogeochemical Processes and Succession/Disturbance Regimes

Each ERU has a combination of biogeochemical processes, seasonal climates, and topoedaphic conditions that has produced a complex of succession/disturbance regimes (table 3.124). The NPP, NAI, CSI, and WSI values shown in table 3.124 are base values, and were not influenced by management. The trend change symbols (+, -, or NC) indicate: increased, reduced, or no change in trend, respectively, from historical to current period conditions for each of the variables. The seasonal climate gradient index (SCI) and topoedaphic index (TEI) did not change unless climate or land-forming changes occurred. The SCI and TEI also accounted for landscape continuity that influenced disturbances across space.

Table 3.124—Relative[1] values for biogeochemical characteristics of Ecological Reporting Units (ERUs) and relationships with succession/disturbance regimes (SDR[2]).

[1]Relative values = values are expressed relative to the highest value among ERUs. The highest value was assigned 1.0.

[2]See table 3.6 for description of succession/disturbance regimes.

[3]Seasonal Climate Gradient Index = index of spring-to-summer evapotranspiration gradient. High values indicate steep gradients that result in high stress and high risk of very dry fuels.

[4]Topoedaphic Index = index of topographic and soil complexity. High values indicate complex terrain and potential for complex fire weather and fuel conditions.

[5]Geographic Area = in reference to subbasin group map and adjacent areas outside the Basin.

[6] – = Decrease.

[7]+ = Increase.

[8]NC = No Change in trend.

As discussed in the proceeding "Biogeochemical Processes" subsection, the NPP, NAI, CSI, and WSI could change as a result of succession or disturbance. Broad native spatial patterns and succession/disturbance regimes can be predicted at multiple scales based on the differences between the six indices (NPP, NAI, CSI, WSI, SCI, and TEI).

Current succession/disturbance regimes could be spatially predicted based on ERU, PVG composition and physiognomic type composition, native composition of succession/disturbance regimes, and recent history of management and disturbance. This information provides a means of stratifying regional and subregional areas and disturbances at multiple spatial and temporal scales, without the need for a current vegetation map, which would require continual updating. Management prescriptions could then be designed to achieve a desired succession/disturbance regime. A set of prescriptions could be applied during project planning or implementation, which would promote coarse- or fine-scale objectives. Additionally, this information provides managers the tools necessary for applying an ecological and landscape systems approach to understanding vegetation and disturbance processes, and potential responses.

The Blue Mountains ERU is quite different from any of the other forest-PVG dominated ERUs. The Blue Mountains ERU occurs in a transition area between the Cascade Mountain environments and central Rocky Mountain environments. The Blue Mountains ERU has moderate NPP and NAI with high carbon stress and moderate water stress in comparison to other ERUs. There is a moderate gradient from moist winter to dry summer conditions, and topoedaphic conditions are complex. These conditions produced an inherent succession/disturbance regime that is dominated by a complex of moderate-cycle and frequent-maintenance regimes. Fire exclusion and timber harvesting of the large, shade-intolerant, and fire-, insect- and disease-resistant trees shifted the succession/disturbance regime to one dominated by a complex of long- and retrogressive-cycle regimes. These changes caused an associated decline in NPP and NAI with increases in both carbon and water stress.

The forest PVGs of the three ERUs located in the central Rocky Mountains (that is, the Central Idaho Mountains, Snake Headwaters, and Upper Clark Fork ERUs) have relatively similar characteristics. They generally have moderate NPP, low NAI, and moderate carbon and water stress. The seasonal gradient is moderate to high with cold and moist winters, to warm and dry summers.

The native succession/disturbance regimes of the three central Rocky Mountains ERUs were a complex, dominated by moderate-, accelerated-, and long-cycle regimes. Fire exclusion, traditional timber harvest activities, loss of whitebark pine to blister rust, widespread growing-season livestock grazing, and invasion by exotic forb and grass species, resulted in a shift to a system dominated by retrogressive- and long-cycle regimes. In general, the Upper Clark Fork ERU has been more substantially affected by fire exclusion, traditional timber harvest activities, and exotic plant invasion than the Central Idaho Mountains or Snake Headwaters ERUs. In general, the Snake Headwaters and Upper Clark Fork ERUs have been more affected by widespread growing-season livestock grazing, and exotic plant invasions than the Central Idaho Mountains ERU.

The associated changes of biogeochemical processes included declining trends of NPP and NAI, and increased trends in carbon or water stress in the Central Idaho Mountains and Upper Clark Fork ERUs (table 3.124). Opposite trends were detected in the Snake Headwaters ERU as a result of its inherently low NAI (caused by low average temperatures). The primary differences between the Central Idaho Mountains ERU and the Upper Clark Fork ERU were related to topography and moisture.

The Northern Glaciated Mountains and Lower Clark Fork ERUs are located in the northern Rocky Mountains. They share characteristics with northern temperate latitude systems that

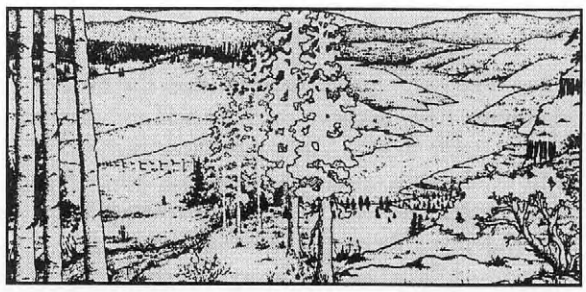
developed on soils and landforms greatly influenced by continental glaciation, mountain glaciation, and erosional processes. Both ERUs have high NPP, moderate NAI, high carbon stress, and low water stress. They also have a moderate gradient in available precipitation from winter to the summer growing season, and moderate to high topoedaphic complexity.

For the northern Rocky Mountains ERUs, the native succession/disturbance regimes were dominated by accelerated- and irregular-cycle regimes. Fire exclusion, traditional timber harvest activities, loss of western white pine and whitebark pine from blister rust, and invasions by exotic forb species resulted in a shift to a system dominated by moderate- and retrogressive-cycle regimes. In general, the Lower Clark Fork ERU has been more substantially affected by fire exclusion and traditional harvest than the Northern Glaciated Mountains ERU. The changes in biogeochemical processes include declining trends of NPP and NAI, and increasing trends in carbon and water stress. The primary differences between the two ERUs are higher water stress and more complex topoedaphic conditions in the Northern Glaciated Mountains ERU.

The Northern Cascades and the Southern Cascades ERUs share characteristics with northern temperate latitude systems that developed on soils and landforms highly influenced by geologic uplift, volcanos, continental glaciation in the north, mountain glaciation in the south, and erosional processes. The two Cascade Mountains ERUs have high NPP, moderate NAI, high carbon stress, and low water stress, which is very similar to the ERUs of the northern Rocky Mountains. However, the Cascade Mountains ERU has a very steep precipitation gradient associated with wet winters and very dry summers. Topoedaphic complexity is also very high as a result of steep elevational gradients, narrow valleys, and rugged terrain.

The Cascade Mountains ERUs, had native succession/disturbance regimes dominated by moderate- and irregular-cycle regimes. Fire exclusion, traditional harvest activities, and exotic plant invasion (particularly in the eastern portion of the ERUs) resulted in a shift to a system dominated by long- and retrogressive-cycle regimes. In general, the Southern Cascades ERU has been more substantially affected by fire exclusion and traditional harvest activities than the Northern Cascades ERU. The associated changes of biogeochemical processes include declining trends of NPP and NAI, and increasing trends in carbon and water stress. The Northern Cascades ERU has slightly higher NPP and CSI, slightly lower NAI and WSI, a somewhat steeper seasonal climate gradient and more complex topoedaphic conditions than the Southern Cascades ERU.

The Upper Klamath ERU is relatively unique in that it is located in a transition area between the temperate mountain climates of the Cascades and the warmer semi-desert mountain climates of the south. NPP is quite low, NAI is moderate, carbon stress is low, and water stress is very high in the Upper Klamath ERU. The seasonal gradient from low winter precipitation to low summer precipitation is moderate. The average growing-season temperatures are high and the terrain is relatively gentle. Although the characteristics of the Upper Klamath ERU are very similar to the non-forest dominated ERUs of the Intermountain Basin, it is dominated by forests, that have adapted to the topoedaphic conditions and drier climate more similar to the Sierra Mountains to the south.



The native succession/disturbance regimes of the Upper Klamath ERU was dominated by moderate- and irregular-cycle regimes. Fire exclusion and traditional harvest activities resulted in a shift to a system dominated by moderate- and long-cycle regimes. Invasion and abundance of exotic annual grasses into this ERU has resulted in short-cycle regimes. The associated changes of biogeochemical processes include a decline of NPP and NAI, and an increase of carbon and water stress.

The non-forest dominated ERUs all have similar characteristics and are located in the Intermountain Basin geographic area. They include the Columbia Plateau, Northern Great Basin, Owyhee Uplands,

and Upper Snake ERUs. These ERUs generally have low NPP, moderate to high NAI, low to moderate CSI, and high WSI. Seasonal climate gradients (from winter to summer) varied from low to moderate, while topoedaphic variability is generally low. The primary differences between the Columbia Plateau ERU and other Intermountain Basin ERUs are: (1) lower topoedaphic complexity, (2) slightly lower water stress, and (3) the presence of wind-deposited, deep loess, and productive soils in the Palouse region of the Columbia Plateau ERU. The Northern Great Basin and Upper Snake ERUs have the highest water stress of the four Intermountain Basin ERUs. The Owyhee Uplands ERU has the steepest gradient from moist winter conditions to very dry summer conditions. We suspect this is a result of interactions of climate and soil conditions.

These non-forest ERUs had a native succession/disturbance regimes that were dominated by frequent-maintenance and moderate-cycle regimes. The combination of fire exclusion, extensive selective grazing of perennial grasses by livestock during the growing season, agricultural development, and exotic forb and annual grass invasions has altered native regimes. Current succession/disturbance regim and Upper Snake ERUs have been altered more by agricultural development than the Northern Great Basin and Owyhee Uplands ERUs. All four of these non-forest ERUs were altered substantially by excessive livestock grazing pressure in the historical period.

REGIONAL AND ECOLOGICAL REPORTING UNIT COVER TYPE TRENDS

We reported the broad-scale trends of cover types from the historical to the current period for the Basin as a whole and by the 13 Ecological Reporting Units within the Basin. When a cover type was reported absent from the historical or current periods this means that it was not detectable with 1-km^2 resolution data. It may, however, be detectable with finer scale data.

The Basin

The richness of cover types increased between the historical and current periods due to the addition of three anthropogenic cover types [urban, exotic forbs/annual grass, and cropland/hay/pasture (hereafter referred to as croplands); table 3.125]. We did not detect measurable changes in areal extent of the alpine tundra, barren, Oregon white oak (*Quercus garryana*), red fir (*Abies magnifica*), or water cover types. Ecologically significant changes were detected for 66 and 34 percent of the cover types relative to class and the Basin, respectively. Two cover types (western white pine and whitebark pine/subalpine larch) were virtually eliminated between the historical and current periods, experiencing a greater than 95 percent decline. Only the barren, lodgepole pine, and antelope bitterbrush/bluebunch wheatgrass (*Purshia tridentata/Agropyron spicatum*) (hereafter referred to as bitterbrush/bluebunch wheatgrass) cover types occurred within their median historical ranges during the current period.

Transition matrices (Jones 1996) indicate that agricultural development was largely responsible for the substantial areal declines of the fescue (*Festuca* spp.)-bunchgrass, wheatgrass bunchgrass, big sagebrush (*Artemisia tridentata*), and native forb cover types. Similarly, nearly 12 percent of the mountain big sagebrush (*Artemisia tridentata vaseyana*) cover type was also converted to agricultural cover types, although most of its decline was attributable to the encroachment of the juniper/sagebrush cover type. Another major change that occurred in non-forest cover types was a transition to the exotic forbs/annual grass cover type. The increase in the exotic forbs/annual grass cover type occurred at the expense of the big sagebrush cover type, and to a lesser extent to the wheatgrass bunchgrass, mountain big sagebrush, and fescue-bunchgrass cover types.

Our observed changes of forest cover types were dominated by the transition of early-seral, shade-intolerant tree species to shade-tolerant tree species. For example, the areal decline of the interior ponderosa pine cover type was attributable to increasing areas of the grand fir/white fir (*Abies grandis/A. concolor*) and interior Douglas-fir cover types; areal declines of the western larch cover type was due to increases of the Douglas-fir, lodgepole pine, or grand fir/white fir cover types; a large proportion of the western white pine cover type was converted to the grand fir/white fir cover type; and a large proportion of the whitebark pine cover type was converted to the Engelmann spruce (*Picea engelmannii*)/subalpine fir cover type.

Blue Mountains ERU

Cover type richness decreased within the Blue Mountains ERU between the historical and current periods (table 3.126). Although three anthropogenic cover types appeared (cropland, exotic forbs/annual grass, and urban) in the current period, four endemic cover types were not detected [bitterbrush/bluebunch wheatgrass, cottonwood/willow (*Populus trichocarpa/Salix*), western larch, and whitebark pine/subalpine larch].

We detected ecologically significant trends of 56 and 41 percent of the cover types relative to class and the Blue Mountains ERU, respectively (table 3.126). Only the alpine tundra, interior Douglas-fir, mountain mahogany (*Cercocarpus ledifolius*), native forb, and water cover types occurred within their median historical ranges during the current period. However, the departures of eight of the cover types were not ecologically significant.

The cover type composition within the Blue Mountains ERU was most affected by areal increases of the croplands and grand fir/white fir cover types, and areal declines of the fescue-bunchgrass and interior ponderosa pine cover types. The cover type transition matrix indicates that 41 percent of the fescue-bunchgrass type was converted to the croplands cover type (Jones 1996). Other areas converted to agricultural uses were derived predominantly from the big sagebrush, mountain big sagebrush, and wheatgrass bunchgrass cover types. The transition matrix also indicates that the loss of the interior ponderosa pine cover type was mostly attributable to a conversion into the grand fir/white fir cover type, and to a lesser degree, the interior Douglas-fir cover type.

Central Idaho Mountains ERU

We detected an increase of cover type richness within the Central Idaho Mountains ERU between the historical and current periods (table 3.127). Although three endemic cover types (bitterbrush/bluebunch wheatgrass, native forb, and whitebark pine/subalpine larch) were not detected, five additional cover types appeared during the current period. Three of the five new cover types detected in the current period were anthropogenic (croplands, exotic forbs/annual grass, and urban), while the remaining two were the mountain hemlock (*Tsuga mertensiana*) and western redcedar/western hemlock cover types. Ecologically significant trends relative to class and the Central Idaho Mountains ERU were detected for 55 and 36 percent of the cover types, respectively. Similarly, the departures of 39 percent of the cover types from their median historical ranges were ecologically significant.

The Central Idaho Mountains ERU was dominated by the areal declines of the wheatgrass bunchgrass and interior Douglas-fir cover types, and the increased areal extent of the croplands, Engelmann spruce/subalpine fir, grand fir/white fir, and shrub or herb/tree regen cover types (table 3.127; Jones 1996). Approximately 53 percent of the Douglas-fir type was converted primarily to the shrub or herb/tree regen, lodgepole pine, Engelmann spruce/subalpine fir, and grand fir/white fir cover types. Similarly, the substantial areal decline of the wheatgrass bunchgrass cover type was primarily the result of conversions into the mountain big sagebrush (34%), big sagebrush (20%), or croplands (19%) cover types.

Columbia Plateau ERU

Between the historical and current periods, five additional cover types were documented, while three were not detected within the Columbia Plateau ERU (table 3.128). The three cover types eliminated included trace amounts of the native forb, western white pine, and whitebark pine/subalpine larch cover types. The five cover types that appeared between the historical and current periods included three anthropogenic cover types (croplands, exotics/annual grass, and urban) and trace amounts of the mountain hemlock and western redcedar/western hemlock cover types.

We detected ecologically significant trends relative to class and the Columbia Plateau ERU for 46 and 20 percent of the cover types, respectively (table

[1]Historical Area = circa 1850 to 1900 (initiated model simulation); Historical Minimum = minimum value from 400-year simulation output; Historical Maximum = maximum value from 400-year simulation output; Current Area = circa 1991.

[2]Class change = percent change relative to the cover type.

[3]ERU change = percent change of the Ecological Reporting Unit (ERU) attributable to the cover type change.

[4]Departure class = index of current areal extent of broad-scale cover types with respect to their historical ranges. Classes: (1) is < historical minimum; (2) is ≥ historical minimum but < median 75% historical range; (3) is within median 75% historical range; (4) is >median 75% historical range and ≤ historical maximum; (5) is > historical maximum.

[5]T = Trace amount ≤ 0.01%.

[6]NA = Not Applicable since the cover type did not exist during the historical period.

*Ecologically significant changes.

3.128). Similarly, 8 of 35 cover types had significant departures from their median historical ranges. Conversely, 10 cover types (alpine tundra, bitterbrush/bluebunch wheatgrass, cottonwood/willow, interior Douglas-fir, interior ponderosa pine, mixed-conifer woodlands, mountain hemlock, shrub or herb/tree regen, water, and western larch) occurred within their median historical ranges during the current period.

Cover type transitions within the Columbia Plateau ERU were dominated by the agricultural conversion of 46 percent of the big sagebrush, 79 percent of the wheatgrass bunchgrass, and 91 percent of the fescue-bunchgrass cover types (Jones 1996). In fact, the croplands cover type composed nearly 45 percent of the Columbia Plateau ERU during the current period. The decline in mountain big sagebrush was primarily attributable to encroachment by western juniper and the associated conversion to the juniper/sagebrush cover type. This transition was most notable in the southern portion of the Columbia Plateau ERU (maps 3.45 and 3.46).

Lower Clark Fork ERU

The richness of cover types within the Lower Clark Fork ERU increased between the historical and current periods (table 3.129). Although two cover types (mixed-conifer woodlands and whitebark pine/subalpine larch) were not detected during this period, five new types (croplands, exotics/annual grass, urban, mountain hemlock, and western redcedar/western hemlock) appeared within the Lower Clark Fork ERU.

We detected ecologically significant trends for 41 and 36 percent of the cover types relative to class and the Lower Clark Fork ERU, respectively (table 3.129). Only three cover types (Engelmann spruce/subalpine fir, interior Douglas-fir, and western larch) occurred within their median historical ranges during the current period. Although we detected substantial departures for the other 19 cover types, only 8 of them were ecologically significant.

The compositional changes of cover types that affected the Lower Clark Fork ERU to the greatest extent involved areal increases of the grand fir/white fir and shrub or herb/tree regen cover types, and areal declines of the interior ponderosa pine and western white pine cover types. The areal extent of the grand fir/white fir cover type increased by more than 5,700 percent and dominated the ERU during the current period. Conversely, the western white pine cover type was nearly eliminated, as its coverage in the Lower Clark Fork ERU declined from approximately 27 percent to near zero. Cover type transitions were dominated by the nearly total conversion of the western white pine cover type to the grand fir/white fir, western larch, and shrub or herb/tree regen cover types, and the conversion of 66 percent of the interior ponderosa pine cover type to the grand fir/white fir type (Jones 1996).

Northern Cascades ERU

The richness of cover types within the Northern Cascades ERU increased between the historical and current periods (table 3.130). During this period, three anthropogenic cover types appeared (cropland, exotic forbs/annual grass, and urban), while the salt desert shrub cover type was not detected.

We detected ecologically significant trends with respect to class and the Northern Cascades ERU for 55 and 39 percent of the cover types, respectively (table 3.130). Of the 33 cover types detected within the ERU, only the chokecherry/serviceberry/rose (*Prunus virginiana/Amelanchier alnifolia/Rosa* spp.), interior ponderosa pine, water, and whitebark pine/subalpine larch cover types occurred within their median historical ranges during the current period. However, more than 50 percent of the substantial departures from the median historical range were not ecologically significant.

The compositional changes of cover types in the Northern Cascades ERU were dominated by the areal decline of the Engelmann spruce/subalpine fir, interior ponderosa pine, western larch, and whitebark pine cover types, and the areal increase

Map 3.45—Historical distribution of western juniper in the Basin, based on the historical extent of the juniper-sagebrush and juniper woodland cover types in the Basin.

Map 3.46—Current distribution of western juniper in the Basin, based on the current period extent of the juniper-sagebrush and juniper woodland cover types in the Basin.

[1]Historical Area = circa 1850 to 1900 (initiated model simulation); Historical Minimum = minimum value from 400-year simulation output; Historical Maximum = maximum value from 400-year simulation output; Current Area = circa 1991.

[2]Class change = percent change relative to the cover type.

[3]ERU change = percent change of the Ecological Reporting Unit (ERU) attributable to the cover type change.

[4]Departure class = index of current areal extent of broad-scale cover types with respect to their historical ranges. Classes: (1) is < historical minimum; (2) is ≥ historical minimum but < median 75% historical range; (3) is within median 75% historical range; (4) is >median 75% historical range and ≤ historical maximum; (5) is > historical maximum.

[5]NA = Not Applicable since the cover type did not exist during the historical period.

[6]Trace = Trace amount ≤ 0.01%.

*Ecologically significant changes.

of the croplands, lodgepole pine, and Pacific silver fir (*Abies amabilis*)/mountain hemlock cover types. The transition matrix (Jones 1996) indicates that the Engelmann spruce/subalpine fir cover type converted primarily to the Pacific silver fir/mountain hemlock and lodgepole pine cover types; the interior ponderosa pine cover type converted to either grand fir/white fir or interior Douglas-fir cover types; the western larch cover type converted into interior Douglas-fir cover type; and the whitebark pine cover type converted into Engelmann spruce/subalpine fir cover type. Similarly, the areal increase of the croplands cover type occurred primarily at the expense of the big sagebrush and fescue-bunchgrass cover types.

Northern Glaciated Mountains ERU

Cover type richness increased between the historical and current periods in the Northern Glaciated Mountains ERU (table 3.131). Five additional cover types appeared (croplands, exotics/annual grass, urban, mountain hemlock, and western redcedar/western hemlock), while the whitebark pine/subalpine larch cover type was not detected in the current period. In addition to the whitebark pine/subalpine larch cover type, nearly all of the big sagebrush and cottonwood/willow cover types were converted to other types between the historical and current periods.

Ecologically significant trends relative to class and the Northern Glaciated Mountains occurred in 46 percent of the cover types (table 3.131). Of the 28 cover types detected in the ERU, the areal extents of only the barren, bitterbrush/bluebunch wheatgrass, Engelmann spruce/subalpine fir, mixed-conifer woodlands, and mountain hemlock cover types occurred within their median historical ranges. Although we detected substantial departures from their median historical ranges for most cover types, only 54 percent of the departures were ecologically significant relative to the composition of types within the Northern Glaciated Mountains ERU.

The composition of the Northern Glaciated Mountains ERU was affected predominantly by the areal increase of the croplands, grand fir/white fir, and interior Douglas-fir cover types, and areal declines of the fescue-bunchgrass, interior ponderosa pine, and western larch cover types (table 3.131; Jones 1996). The transition matrix indicated that agricultural development was largely responsible for the areal declines of the big sagebrush, fescue-bunchgrass, and interior ponderosa pine cover types. Similarly, 46 percent of the western larch and 33 percent of the interior ponderosa pine cover types were converted to either grand fir/white fir or interior Douglas-fir cover types.

Northern Great Basin ERU

The richness of cover types did not vary between the historical and current periods within the Northern Great Basin ERU (table 3.132). However, three cover types appeared (croplands, exotic forbs/annual grass, and grand fir/white fir), while three cover types (native forb, Sierra Nevada mixed-conifer, and western larch) were converted to other types during that time interval.

We detected ecologically significant class trends for 10 cover types (table 3.132). However, ecologically significant changes relative to the Northern Great Basin ERU occurred due to the changes of five cover types (big sagebrush, croplands, exotic forbs/annual grass, juniper/sagebrush, and mountain big sagebrush). The current period areal extent of most (84%) cover types departed substantially from their median historical ranges. However, only the departures of five cover types (croplands, exotic forbs/annual grass, fescue-bunchgrass, juniper/sagebrush, and mountain big sagebrush) were ecologically significant.

The compositional changes of the Northern Great Basin ERU were dominated by the areal increases in the cropland, exotic forbs/annual grass, and juniper/sagebrush cover types, and the areal declines of the big sagebrush, mountain big sagebrush, and salt desert shrub cover types (table 3.132; Jones 1996). Agricultural development was

largely responsible for the substantial decline of the salt desert shrub cover type, and relatively smaller declines of the wheatgrass bunchgrass and fescue-bunchgrass cover types. The increase of the exotic forbs/annual grass cover type occurred predominantly in the big sagebrush cover type, and to a lesser extent in the mountain big sagebrush cover type. The decline in mountain big sagebrush was primarily attributable to encroachment by western juniper and the conversion to the juniper/sagebrush cover type.

Owyhee Uplands ERU

The richness of cover types within the Owyhee Uplands ERU increased between the historical and current periods (table 3.133). Three anthropogenic cover types appeared (cropland, exotic forbs/annual grass, and urban), while two cover types (lodgepole pine and native forb) disappeared during this time interval.

We detected ecologically significant trends of 38 and 10 percent of the cover types relative to class and the Owyhee Uplands ERU, respectively (table 3.133). Although the areal extents of 22 of the 29 cover types occurred outside their median historical ranges during the current period, the departures of only six cover types were ecologically significant.

The composition of the Owyhee Uplands ERU was affected to the greatest extent by the areal decline of the big sagebrush cover type, and the areal increases of the croplands and exotic forbs/annual grass cover types (table 3.133; Jones 1996). Not surprisingly, the transition matrix indicates that agricultural development and the large increase in exotic forbs/annual grass cover type were responsible for the substantial reduction in area of the big sagebrush cover type. Although we observed a 21 percent decline of the big sagebrush cover type across 11 percent of the Owyhee Uplands ERU, the big sagebrush type continued to occur within its median historical range during the current period.

Snake Headwaters ERU

The richness of cover types within the Snake Headwaters ERU decreased between the historical and current periods (table 3.134). Although three anthropogenic cover types (croplands, exotic forbs/annual grass, and urban) appeared, four endemic cover types (chokecherry/serviceberry/rose, cottonwood/willow, mixed-conifer woodlands, and native forb) were not detected in the current period.

Of the 28 cover types observed within the Snake Headwaters ERU, we detected ecologically significant trends for 46 and 32 percent of the types relative to class and the Snake Headwaters ERU, respectively (table 3.134). Although we observed substantial departures from the median historical range in all but five cover types, these departures were ecologically significant for only 36 percent of the cover types.

The composition of cover types within the Snake Headwaters ERU was affected predominantly by the areal increases of the croplands and interior Douglas-fir cover types; and the areal declines of the big sagebrush and lodgepole pine cover types, and to a lesser degree, the mountain big sagebrush, and shrub or herb/tree regen cover types (table 3.134; Jones 1996). The areal increase of the interior Douglas-fir cover type was derived mostly from the lodgepole pine, mountain big sagebrush, shrub or herb tree/regen, and Engelmann spruce/subalpine fir cover types. The 67 percent loss of the lodgepole pine cover type was attributable to gains in the interior Douglas-fir and Engelmann spruce/subalpine fir cover types. Nearly all of the big sagebrush and mountain big sagebrush cover types were eliminated within the Snake Headwaters ERU. Agricultural conversion was responsible for the 84 percent areal decline of the big sagebrush cover type, whereas encroaching Douglas-fir converted 89 percent of the mountain big sagebrush cover type.

[6]NA = Not Applicable since the cover type did not exist during the historical period.

*Ecologically significant changes.

Southern Cascades ERU

Overall, the richness of cover types increased within the Southern Cascades ERU between the historical and current periods (table 3.135). Four cover types appeared (croplands, exotic forbs/annual grass, urban, and mountain mahogany), while three cover types disappeared (cottonwood/willow, salt desert shrub, and Sierra Nevada mixed-conifer) during this time interval. In addition, nearly all of the western larch cover type was eliminated between the historical and current periods.

We detected ecologically significant trends relative to class and the Southern Cascades ERU with 41 and 22 percent of the cover types, respectively (table 3.135). Seven cover types (alpine tundra, barren, chokecherry/serviceberry/rose, Engelmann spruce/subalpine fir, mixed-conifer woodlands, shrub or herb/tree regen, and Pacific silver fir/mountain hemlock) occurred within their median historical ranges during the current period. Although we observed substantial departures from the median historical ranges for most cover types, only the departures of 30 percent of the cover types were ecologically significant relative to the composition of the Southern Cascades ERU.

The composition of the Southern Cascades ERU was predominantly affected by the decline of the interior ponderosa pine cover type, and the increases of the cropland, interior Douglas-fir, and grand fir/white fir cover types (table 3.135; Jones 1996). The transition matrix indicates that approximately 30 percent of the interior ponderosa pine cover type transitioned into interior Douglas-fir and grand fir/white fir cover types. The transitions of non-forest cover types were dominated by the agricultural conversion of the big sagebrush cover type.

Upper Clark Fork ERU

The richness of cover types within the Upper Clark Fork ERU increased between the historical and current periods (table 3.136). Three additional cover types appeared (croplands, exotic forbs/annual grass, urban), while two cover types (juniper/sagebrush and whitebark pine/subalpine larch) were not detected during the current period. The western larch cover type was nearly eliminated during this period as well.

We observed ecologically significant trends relative to class and the Upper Clark Fork ERU with 46 and 37 percent of the cover types, respectively (table 3.136). Seven of 26 cover types occurred within their median historical ranges during the current period. The departures of 39 percent of the cover types were ecologically significant.

The composition of the Upper Clark Fork ERU was most affected by the areal increases of the cropland and Engelmann spruce/subalpine fir cover types, and the areal declines of the wheatgrass bunchgrass, fescue-bunchgrass, and interior Douglas-fir cover types (table 3.136; Jones 1996). The transition matrix indicates that approximately 18 percent of the fescue-bunchgrass and 69 percent of the wheatgrass bunchgrass cover types were converted by agricultural development between the historical and current periods. An additional 47 percent of the fescue-bunchgrass cover type was eliminated by the encroachment of interior ponderosa pine and interior Douglas-fir cover types. Changes in forest cover types were dominated by transitions of the lodgepole pine and interior Douglas-fir cover types into the Engelmann spruce/subalpine fir cover type.

Upper Klamath ERU

Although the richness of cover types within the Upper Klamath ERU did not change between the historical and current periods, the composition of cover types changed substantially (table 3.137). Three anthropogenic cover types appeared (cropland, exotic forbs/annual grass, and urban), while three endemic cover types (salt desert shrub, western larch, and whitebark pine/subalpine larch) were not detected in the current period.

We detected ecologically significant trends relative to class and the Upper Klamath ERU for 49 and 30 percent of the cover types, respectively (table 3.137). During the current period, the areal extent of only six cover types (alpine tundra, barren,

chokecherry/serviceberry/rose, Engelmann spruce/subalpine fir, mixed-conifer woodlands, and shrub or herb/tree regen) occurred within their median historical ranges. Although we observed substantial departures of most cover types from their median historical ranges, only the departures of 33 percent of the cover types were ecologically significant.

Upper Klamath ERU composition was predominantly affected by the areal increases of the cropland, interior Douglas-fir, and juniper/sagebrush cover types; and the areal declines of the fescue-bunchgrass, interior ponderosa pine, and mountain big sagebrush cover types (table 3.137; Jones 1996). The transition matrix indicates that the 95 percent decline of the fescue-bunchgrass cover type that we observed was the result of transitions to the interior ponderosa pine (94%), croplands (33%), and mixed-conifer woodlands (17%) cover types (Jones 1996). Nearly 25 percent of the interior ponderosa pine cover type changed into the interior Douglas-fir cover type. Although somewhat less significant with respect to the Upper Klamath ERU, the transition matrix indicates that approximately 56 percent of the mountain big sagebrush and 99 percent of the low sagebrush (*Artemisia arbuscula*) cover types changed into the juniper/sagebrush cover type.

Upper Snake ERU

The richness of cover types within the Upper Snake ERU increased between the historical and current periods (table 3.138). Three anthropogenic cover types appeared (cropland, exotic forbs/annual grass, and urban), and two endemic cover types (mixed-conifer woodlands and native forb) were not detected during the current period.

We detected ecologically significant trends relative to class and the Upper Snake ERU with 35 and 23 percent of the cover types, respectively (table 3.138). Although only 6 of 26 cover types occurred within their median historical range during the current period, most departures were not ecologically significant. Ecologically significant departures were evident with 27 percent of the cover types.

The composition of cover types within the Upper Snake ERU was primarily influenced by the changes of three cover types (table 3.138; Jones 1996). A significant decline of the big sagebrush cover type occurred across 42 percent of the ERU, whereas areal increases of the croplands and exotic forbs/annual grass cover types affected nearly 43 percent of the ERU. Forty-one percent of the areal decline of the big sagebrush cover type was a result of agricultural development. Lesser amounts of the big sagebrush cover type were converted into the exotic forbs/annual grass (10%) and wheatgrass bunchgrass (5%) cover types. Virtually all of the areal increase of the croplands cover type occurred at the expense of the big sagebrush cover type.

Cover type discussion

Differing geographic scales did not seem to substantially affect cover type trends within our assessment area. That is, the cover type trends observed within the 13 ERUs generally reflected the trends that occurred within the Basin as a whole. Furthermore, with the exception of the bitterbrush/bluebunch wheatgrass, Engelmann spruce/subalpine fir, lodgepole pine, and shrub or herb/tree regen cover types, there was little variability of the cover type departure classes among the 13 ERUs. Although the departure classes of the bitterbrush/bluebunch wheatgrass, Engelmann spruce/subalpine fir, and lodgepole pine varied among the ERUs, the ERUs that seemed to have the most conflicting trends were those whose departures were not ecologically significant. For example, the departure classes of the lodgepole pine cover type indicated that it occurred within or above its median historical range for the majority of ERUs. Conversely, the areal extent of lodgepole pine cover type within the Columbia Plateau, Snake Headwaters, and Upper Snake ERUs was well below its median historical ranges. However, only the observed departure class of the Snake Headwaters ERU was ecologically significant. The shrub or herb/tree

[5]NA = Not Applicable since the cover type did not exist during the historical period.

*Ecologically significant changes.

regen cover type occurred well above its median historical range in four ERUs, within its median historical range in six ERUs, and well below its median historical range in three ERUs.

Agricultural development significantly changed the composition of cover types within the Basin, and within all of the 13 ERUs. Approximately 16 percent of the Basin was converted to the croplands cover type. Even the least impacted ERUs (for example, the Lower Clark Fork and Northern Great Basin ERUs) lost 2 to 3 percent of their area to agricultural uses. Conversely, agricultural development occurred across 33 and 45 percent of the Upper Snake and Columbia Plateau ERUs, respectively. Not surprisingly, most of the agricultural conversions occurred within non-forest cover types, and were largely responsible for the significant areal declines of the endemic grassland and forb cover types (that is, the wheatgrass bunchgrass, fescue-bunchgrass, and native forb cover types) and also for a large proportion of the observed declines in many shrubland cover types (for example, the big sagebrush, mountain big sagebrush, and salt desert shrub cover types).

Within forest environments, cover type compositional changes were predominantly related to the replacement of cover types dominated by shade-intolerant species with resistance to fire, insects, and diseases, by cover types dominated by shade-tolerant species with higher susceptibilities to fires, insects, and diseases. With few exceptions, we observed significantly declining trends for the cottonwood/willow, interior ponderosa pine, western larch, western white pine, whitebark pine/subalpine larch, and whitebark pine cover types throughout the Basin. Conversely, we commonly detected significant increases for the grand fir/white fir, interior Douglas-fir, and western redcedar/western hemlock cover types. These trends were most likely brought about by fire suppression and timber harvesting activities. Fire suppression increased the establishment and development of forest stands that were composed of shade-tolerant species. Conversely, past silvicultural practices commonly targeted the early-seral shade-intolerant species for removal from forest stands.

We detected 37 instances in which a cover type disappeared from an ERU between the historical and current periods. Twelve cover types were involved. Although these cover types disappeared from our broad-scale coverage of the current period, we are not suggesting that they no longer occurred in that region; instead, we are saying that their areal declines within an ERU were to the extent that the cover types no longer represented a dominant component of a 1-square kilometer pixel. In all likelihood, a finer-grained analysis would have detected their presence in the landscape (Henderson-Sellers and others 1985, Meentemeyer and Box 1987). The cover types that experienced the largest declines include whitebark pine/subalpine larch (lost from 7 ERUs), native forb (lost from 6 ERUs), and western larch (lost from 5 ERUs). These cover types were often rare within an ERU during the historical period. In most instances (76%), the historical area of the lost cover type had composed less than 0.5 percent of an ERU (mean = 1.10%, sd = 4.40). However, the western white pine cover type was eliminated from the Lower Clark Fork ERU even though it composed nearly 27 percent of the region during the historical period. Four of the 12 cover types (native forb, Sierra Nevada mixed-conifer, western white pine, and whitebark pine/subalpine larch), which were frequently lost from various ERU landscapes, have experienced at least 90 percent declines within the Basin as a whole.

We compared the trends of our broad-scale forest and woodland cover types within ERUs to the trends of mid-scale forest and woodland cover types reported by Hessburg and others (1996a). As expected, there were some discrepancies between the two data sets. However, considering that the two analyses were conducted at different resolutions (1-km^2 and 4-ha for broad-scale and mid-scale analyses, respectively), and that the trends were assessed across different time periods (approximately 100 to 150 years versus the past 30 to 70 years for broad-scale and mid-scale, respectively), the observed trends were quite comparable. The most common discrepancies between the two analyses included instances where trends were detected at both the broadscale and midscale, but the trends were only significant at the broadscale. These sorts of discrepancies occurred most

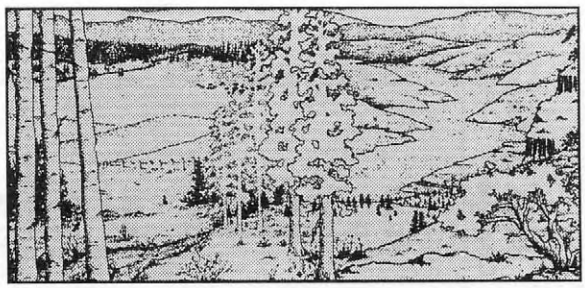
frequently with the grand fir/white fir, lodgepole pine, and western larch cover types within the Central Idaho Mountains, Lower Clark Fork, and Southern Cascades ERUs. Conflicting trends (that is, the broad-scale and mid-scale analyses detected opposite trends) most commonly occurred with the Engelmann spruce/subalpine fir and interior ponderosa pine cover types.

Coarse-grained analyses commonly underestimated cover types occurring in small- to medium-sized patches that did not dominate the spectral response of a particular pixel (Quattrochi and Pelletier 1991). As previously noted, we experienced problems accurately depicting the presence of the aspen, herbaceous wetlands, and shrub wetlands cover types. Our broad-scale mapping of vegetation types also underestimated the extent of plant communities dominated by exotic species. For example, many of the exotic broadleaf forbs (for example, knapweeds, yellow starthistle, and leafy spurge) could have existed in patches too small to dominate a 1-square-kilometer pixel. In addition, we were more likely to detect large patches of communities dominated by exotic annual grasses (for example, cheatgrass and medusahead) where they existed as a monoculture. Where exotic grasses composed portions of the understory shrubland community, the spectral image was typically classified as a shrub cover type (for example, big sagebrush, or mountain big sagebrush). Lastly, even if a patch was large enough to be detected, remote sensing techniques only had a limited capability to differentiate endemic species from exotic species. Examples of broad-scale native cover type conversions to the exotic forbs/annual grass cover type, which we likely failed to document in this analysis and were supported by finer-scale information, include:

1) wheatgrass bunchgrass cover type in the Blue Mountains and Columbia Plateau ERUs to the exotic forbs/annual grass cover type (particularly by yellow starthistle)(Talbott 1987), and
2) fescue-bunchgrass and interior ponderosa pine cover types in the Northern Glaciated Mountains ERU to the exotic forbs/annual grass cover type (particularly by diffuse and spotted knapweed) (Talbott 1987).

Many cover types often incurred substantial class changes, but because they composed relatively minor proportions of a region, their changes did not significantly affect the overall composition of the region. However, that is not to say that these changes did not have significant effects on other components of the ecosystem, or on various ecosystem functions. Rare vegetation communities may contain unique phenotypes and genotypes that may be important for individual, population, and species fitness and consequently, evolutionary processes.

Our historical simulation of cover types suggests that the composition of cover types within an ERU was dynamic. Each ERU contained two to four cover types for which we detected substantial trends between the historical and current periods, even though these cover types still occurred within their median historical range during the current period. Thus, substantial changes of at least some broad-scale cover types seemed to have been the norm, rather than the exception, prior to Euro-American settlement within the Basin. The cover types that appeared to be most dynamic across a region include Engelmann spruce/subalpine fir, interior Douglas-fir, interior ponderosa pine, shrub or herb/tree regen, mixed-conifer woodlands, western larch, fescue-bunchgrass, and bitterbrush/bluebunch wheatgrass.



Inherent to any scale of analysis is the need to summarize data to some geographic unit. For our analysis of broad-scale cover types, we chose to summarize composition and trends at the ERU and Basin levels. We do not imply that the trends we observed would necessarily occur at other analytical scales. Our transition analyses indicate that trends for a specific cover type could differ appreciably within ERUs. This was because the pixels of a specific cover type could change in different ways within an ERU between the historical to the current period (that is, the pixels could stay the same or convert into another cover type). Given this level of variability for specific cover types at the ERU level, we expect that trends for specific cover types at a finer scale would likewise be variable and might be inconsistent with ERU trends.

REGIONAL AND ECOLOGICAL REPORTING UNIT TERRESTRIAL COMMUNITY TRENDS

We reported the changes of the broad-scale terrestrial communities for the Basin as a whole, as well as by the 13 Ecological Reporting Units of the Basin.

The Basin

Richness of terrestrial communities increased by three anthropogenic types (agricultural, exotic herbland, and urban) between the historical and current periods. During the current period, agricultural was the third most dominant community type within the Basin. Out of 21[2] terrestrial communities, alpine, rock/barren, and water did not change between historical and current periods (table 3.139).

We detected significant changes with respect to class for 11 of 21 community types (table 3.139). Ecologically significant negative trends were evident in six terrestrial communities (upland herbland, upland shrubland, early-seral lower montane forest, late-seral lower montane single-layer forest, late-seral lower montane multi-layer forest, and late-seral subalpine multi-layer forest). The early-seral lower montane forest and late-seral lower montane single-layer forest communities declined by more than 75 percent. Conversely, significant positive trends occurred in five terrestrial communities (early-seral subalpine forests, mid-seral lower montane forest, mid-seral montane forest, late-seral subalpine single-layer forest, and upland woodland).

Ecologically significant changes relative to the Basin were apparent with seven terrestrial communities (table 3.139). The agricultural, exotic herbland, mid-seral montane forest, and mid-seral lower montane forest communities increased across substantial areas within the Basin, whereas late-seral lower montane single-layer forest, upland herbland, and upland shrubland communities declined across substantial areas. The decrease in upland shrubland and upland herbland communities accounted for nearly a 21 percent change of the Basin as a whole. Conversions to the agricultural community occurred across 16 percent of the Basin.

The transitions of upland herbland and upland shrubland communities into the agricultural type dominated the changes that occurred in the Basin (table 3.140). Other dominating changes involved the transitions of early- and late-seral forest communities into mid-seral forest communities, which occurred across 9.2 percent of the Basin. Although pixels of upland herbland and upland shrubland transitioned to each other, the net transition favored the upland shrubland community.

[2] There are 24 terrestrial community types found within the Basin, but we were able to assess only 21 of them. Patterns were not assessed for the three riparian community types due to the fact that these types generally occurred in scattered, relatively small- to medium-sized patches, and tended to be underestimated as mapping resolution increased. The historical vegetation layer was developed at a coarser resolution than the current period vegetation layer, creating different biases. Therefore, changes of riparian communities between historical and current periods could not be accurately assessed (see table 3.9 and appendix 3-B for descriptions of terrestrial community types).

Table 3.139—Changes of broad-scale terrestrial communities between historical and current periods within the Basin.

Upland Herbland	Agricultural	6.6
Upland Herbland	Mid-seral Lower Montane Forest	1.3
Upland Herbland	Upland Shrubland	2.1
Upland Shrubland	Agricultural	9.0
Upland Shrubland	Exotic Herbland	1.1
Upland Shrubland	Upland Herbland	1.0
Upland Shrubland	Upland Woodland	1.3

[1]Dominant transitions were those affecting at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of Basin Area (percent) = proporation of landscape affected; area of the landscape in which a terrestrial community changed into another terrestrial community.

The areal extent of all but four (alpine, rock/barren, water, and early-seral montane forest) terrestrial communities occurred outside of their median 75 percent historical range (tables 3.139 and 3.140). However, the departure indices for the mid-seral subalpine forest, late-seral montane single-layer forest, late-seral montane multi-layer forest, and urban communities were not ecologically significant.

A significant shift among the areal extent of early-, mid-, and late-seral forest communities occurred between historical and current time periods. The distribution of mid-seral forest communities increased at the expense of both early- and late-seral forest communities. Late-seral and early-seral forest communities had net declines across 6 and 1 percent of the Basin, respectively (table 3.139). However, as a group, the areal extent of mid-seral forest communities increased across nearly 9 percent of the Basin.

Blue Mountains ERU

During the current period, the agricultural community type was the most dominant type within the Blue Mountains ERU (table 3.141). Of the 20 terrestrial communities we observed in the Blue Mountains ERU, only the alpine and water communities did not change between historical and current periods.

We failed to detect significant changes with respect to class for 50 percent of the terrestrial communities that occurred within the Blue Mountains ERU (table 3.141). Six communities declined significantly (early-seral lower montane forest, late-seral lower montane single-layer forest, late-seral subalpine single-layer forest, mid-seral subalpine forest, upland herbland, and upland shrubland). The late-seral lower montane single-layer forest and mid-seral subalpine forest communities declined by more

than 80 percent. Conversely, significant positive trends occurred within four of the terrestrial communities (early-seral subalpine forest, late-seral montane multi-layer forest, mid-seral lower montane forest, and mid-seral montane forest). The mid-seral montane forest, late-seral montane multi-layer forest, and early-seral subalpine forest communities increased by more than 200, 300, and 600 percent, respectively. Although, the early-seral montane forest, late-seral montane single-layer forest, and late-seral subalpine multi-layer forest communities increased substantially, their trends were not ecologically significant.

Ecologically significant changes relative to the Blue Mountains ERU were apparent in 9 of 20 terrestrial communities (table 3.141). Three communities decreased across significant proportions of the ERU (upland shrubland, upland herbland, and late-seral lower montane single-layer forest), whereas significant increases in area were evident with the agricultural, exotic herbland, early-seral subalpine forest, late-seral montane multi-layer forest, mid-seral lower montane, and mid-seral montane forest communities. The decline of the upland herbland and late-seral lower montane single-layer forest communities occurred across 18 and 15 percent of the Blue Mountains ERU, respectively. Conversely, approximately 17 percent of the ERU was converted to the agricultural community type.

The areal extent of most (60%) terrestrial communities occurred outside of their median 75 percent historical range (table 3.141). Although the urban community type occurred above its historical range, its departure was not ecologically significant.

The areal reduction of the upland shrubland and upland herbland communities was dominated by agricultural conversion (table 3.142). Finer-resolution information, however (Skovlin and Thomas 1995), suggests that substantial areal reduction of the upland shrubland and upland herbland communities was attributable to encroachment by western juniper (that is, the upland woodland community). Virtually all (96%) of the late-seral lower montane single-layer forest type was transformed: 27 percent changed to the mid-seral lower montane forest, 26 percent changed to the mid-seral montane forest, and 22 percent changed to the late-seral montane multi-layer forest community types (Jones 1996). Conversely, the increase in late-seral montane multi-layer and mid-seral forest communities occurred predominantly at the expense of the late-seral lower montane single-layer and mid-seral forest communities.

As a group, the composition of late-seral forest communities declined from 23 to 15 percent of the Blue Mountains ERU (a 35% decline). However, late-seral single-layer forest communities decreased, whereas late-seral multi-layer forest communities increased (table 3.141). The increases in both early- and mid-seral forest communities were ecologically significant.

Central Idaho Mountains ERU

The richness of terrestrial communities of the current period was greater than the historical period due to the addition of three anthropogenic communities (agricultural, exotic herbland, and urban; table 3.143). Of the 21 terrestrial communities occurring within the Central Idaho Mountains ERU, 7 communities occurred within their median 75 percent historical range during the current period (alpine, late-seral montane multi-layer forest, late-seral lower montane multi-layer forest, mid-seral montane forest, rock/barren, upland shrubland, and water). Ecologically significant trends occurred for 10 and 11 community types with respect to class and ERU, respectively. The areal extent of the early-seral lower montane forest, late-seral lower montane single-layer forest, upland herbland, and upland woodland communities decreased by more than 50 percent. In terms of ERU change, the loss of upland herbland communities and the conversion to agriculture affected the largest proportion of the Central Idaho Mountains ERU (9% and 6%, respectively).

[1]Historical Area = circa 1850 to 1900 (initiated model simulation); Historical Minimum = minimum value from 400-year simulation output; Historical Maximum = maximum value from 400-year simulation output; Current Area = circa 1991.

[2]Class change = percent change relative to the terrestrial community.

[3]ERU change = percent change of the ERU attributable to the terrestrial community change.

[4]Departure class = index of current areal extent of broad-scale cover types with respect to their historical ranges. Classes: (1) is < historical minimum; (2) is ≥ historical minimum but < median 75% historical range; (3) is within median 75% historical range; (4) is >median 75% historical range and ≤ historical maximum; (5) is > historical maximum.

[5]NA = Not Applicable; the terrestrial community did not exist during the historical period.

*Ecologically significant changes.

Although substantial class and ERU changes occurred with the late-seral lower montane multi-layer forest and mid-seral montane forest communities, respectively, these changes were not ecologically significant. On the other hand, even though the current period areal extent of the late-seral subalpine multi-layer forest and urban community types occurred outside of their median historical ranges, these departures were not ecologically significant.

The 51 percent areal decline of the upland herbland community was attributed primarily to increases in upland shrubland, agricultural, and mid-seral lower montane forest communities (table 3.144, Jones 1996). The decline in late-seral lower montane single-layer forest communities largely occurred due to transitions into mid-seral montane forest and late-seral montane multi-layer forest communities. Similarly, disturbances converted the mid-seral subalpine forest community to the early-seral subalpine forest community, converted the mid-seral montane forest community to the early-seral subalpine community, and converted the upland woodland community to the upland herbland community. Conversely, successional processes were most likely responsible for the conversions of the early-seral lower montane forest community to the early-seral montane forest, mid-seral montane forest, and mid-seral lower montane forest communities.

Columbia Plateau ERU

We detected 20 broad-scale terrestrial communities within the Columbia Plateau ERU (table 3.145). However, the alpine and late-seral subalpine single-layer forest communities had always been extremely rare in that they never occupied more than a trace amount of the landscape. The current period areal extent of five community types (alpine, early-seral subalpine forest, late-seral montane multi-layer forest, late-seral montane single-layer forest, and water) occurred within their median 75 percent historical ranges. Ecologically significant trends were detected for 10 and 8 communities with respect to class and ERU, respectively. Five communities (early-seral lower montane forest, late-seral lower montane single-layer forest, late-seral subalpine multi-layer forest, mid-seral subalpine forest, and upland herbland) declined by more than 75 percent. Conversely, four communities (late-seral montane single-layer forest, mid-seral montane forest, mid-seral lower montane forest, and upland woodland) increased by more than 100 percent. The areal declines of the upland herbland and upland shrubland communities occurred across approximately 53 percent of the Columbia Plateau ERU. Conversely, approximately 45 percent of the ERU was converted to the agricultural community.

Although we detected substantial class changes of the early-seral subalpine forest, late-seral montane multi-layer forest, and late-seral montane single-layer forest communities, these changes were not ecologically significant (table 3.145). Similarly, the 35 percent increase of the late-seral subalpine single-layer forest community was not deemed significant, as the current period area did not amount to more than a trace amount of the ERU. Using similar logic, we concluded that although the current period areal extent of the late-seral subalpine single-layer forest and urban communities occurred above their median historical ranges, we did not regard these changes as significant.

The dominant causal factor for the loss of upland herbland and upland shrubland communities in the Columbia Plateau ERU was conversion to the agricultural type (table 3.146; Jones 1996). Approximately 94 percent of the late-seral lower montane single-layer forest community was altered by the loss of larger diameter trees and/or an increase in stocking levels of montane species. These forests converted predominantly to mid-seral lower montane (46%), late-seral lower montane multi-layer (18%), or mid-seral montane forest (15%) community types. The encroachment of the upland woodland community (primarily western juniper) into the upland shrubland community occurred across 4 percent of the ERU, and was restricted primarily to the southern portion of this ERU.

Table 3.144—Dominant transitions[1] of terrestrial communities within the Central Idaho Mountains Ecological Reporting Unit (ERU).

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of ERU Area (percent) = proportion of landscape affected; area of the ERU in which a terrestrial community changed into another terrestrial community.

Lower Clark Fork ERU

Nineteen community types were detected within the Lower Clark Fork ERU (table 3.147). However, the exotic herbland community type only occupied a trace amount of the region during the current period, and the upland shrubland community appeared across 0.1 percent of the region during the historical simulations, but did not appear during the historical or current periods. Relative to the historical period, the current period had three additional anthropogenic community types (agricultural, exotic herbland, and urban). Conversely, three community types (late-seral lower montane multi-layer forest, late-seral lower montane single-layer forest, and upland woodland) were no longer evident during the current period. Thus, the richness of terrestrial communities stayed the same between historical and current periods.

Ecologically significant trends relative to class and ERU were apparent with 11 and 9 community types, respectively (table 3.147). Three terrestrial communities (late-seral lower montane multi-layer

*Ecologically significant changes.

Table 3.146—Dominant transitions[1] of terrestrial communities within the Columbia Plateau Ecological Reporting Unit (ERU).

Terrestrial Community		
Historical Period[2]	**Current Period**	**Proportion of ERU Area (%)[3]**
Early-seral Montane Forest	Mid-seral Montane Forest	1.0
Late-seral Lower Montane Single-layer Forest	Mid-seral Lower Montane Forest	1.5
Upland Herbland	Agricultural	23.0
Upland Herbland	Mid-seral Lower Montane Forest	1.2
Upland Herbland	Upland Shrubland	4.2
Upland Shrubland	Agricultural	23.0
Upland Shrubland	Upland Woodland	3.9

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of ERU Area (percent) = proportion of landscape affected; area of the ERU in which a terrestrial community changed into another terrestrial community.

forest, late-seral lower montane single-layer forest, and upland woodland) were lost completely, and the areal extent of four other community types (early-seral lower montane forest, late-seral montane multi-layer forest, late-seral subalpine multi-layer forest, and upland herbland) declined by more than 80 percent.

Successionally, forest communities have transitioned to mid-seral forests. As a whole, late-seral forest communities decreased from 25 to 2 percent of the Lower Clark Fork ERU (a 93% decline), while early-seral forest communities declined 53 percent. Both single- and multi-layer late-seral forest declined. Mid-seral communities, as a whole, increased by 106 percent. The areal extent of two of the three mid-seral forest communities (mid-seral montane forest and mid-seral subalpine forest) increased by more than 100 percent. In fact, the increase of the mid-seral montane forest community occurred across 36 percent of the landscape.

Although substantial areal declines occurred with the early-seral subalpine forest and late-seral subalpine single-layer forest communities these changes were not ecologically significant (table 3.147). Similarly, we did not regard the substantial departures of the exotic herbland, upland shrubland, and urban communities as ecologically significant.

The areal extent of the mid-seral montane forest community increased (table 3.148) largely due to the loss of the late-seral lower montane single-layer forest and mid-seral lower montane forest communities (Jones 1996). In addition, virtually all of the late-seral lower montane single-layer forest type changed to either mid-seral montane or mid-seral lower montane forest communities. Similarly, virtually all of the late-seral lower montane multi-layer forest community was converted to predominantly mid-seral montane or mid-seral lower montane forest communities. A comparable process was evident in subalpine forest communities, where a 95 percent decline of the late-seral subalpine multi-layer forest type was attributable to a subsequent increase of both early- and mid-seral montane forest and subalpine forest communities. Rangeland communities were dominated by the 100 percent conversion of the upland woodland community to the upland herbland community, and the alteration of 87 percent of the upland herbland community by either agricultural development or encroachment by lower montane forest communities.

Northern Cascades ERU

The richness of terrestrial communities increased by three anthropogenic types between historical and current periods (table 3.149). Of 20 terrestrial communities, we observed ecologically significant trends with 11 and 10 communities relative to class and ERU, respectively. The seven community types that had significant declining class trends lost nearly 60 percent or more of their respective areas. The areal decline of the late-seral lower montane single-layer forest community (96%) was the most extensive landscape change within the Northern Cascades ERU.

Although the early-seral lower montane forest community increased by more than 200 percent across 1.2 percent of the Northern Cascades ERU, the change was not ecologically significant (table 3.149). Similarly, the increase of the late-seral montane multi-layer forest across nearly 1.3 percent of the ERU did not deviate substantially from historical conditions. Conversely, although the exotic herbland and urban community types deviated substantially from their median historical ranges, these changes were not ecologically significant.

Virtually all of the decline in the late-seral lower montane single-layer forest community was due to transitions to predominantly younger stands of mid-seral lower montane and mid-seral montane forest communities (table 3.150, Jones 1996). Other forest communities were also dominated by changes to younger forests. An increase of the early-seral montane forest community occurred largely at the expense of mid-seral montane and mid-seral subalpine forest communities. However, the increase in the mid-seral lower montane forest community was derived from both ends of the

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of the ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

successional pathway— mostly originating from the late-seral lower montane single-layer forest and early-seral montane forest communities, and to a lesser degree, the upland shrubland communities. With respect to rangeland communities, the 6 percent of the Northern Cascades ERU that was converted to agriculture was largely derived from the upland shrubland and upland herbland communities. The majority of the 74 percent loss of the upland shrubland community from the historic to the current period was attributable to conversion to the agricultural (38%), mid-seral lower montane forest (19%), and upland woodland (12%) communities.

As a group, late-seral forest communities decreased from 28 to 13 percent of the ERU (a 54% decline; table 3.149). We detected significant declines in both single- and multi-layer late-seral forest communities. Conversely, both early- and mid-seral forest communities increased.

Northern Glaciated Mountains ERU

The richness of terrestrial communities increased by three anthropogenic types (agricultural, exotic herbland, and urban) between the historical and current periods (table 3.151). Of the 20 terrestrial communities that occurred in the Northern Glaciated Mountains ERU, the areal extent of only three (rock/barren, upland woodland, and water) existed within their median historical ranges during the current period. Ecologically significant trends were detected for 14 and 13 community types with respect to class and ERU, respectively. The areal extent of eight community types decreased by more than 75 percent. The late-seral montane single-layer forest, late-seral lower montane single-layer forest, and late-seral subalpine multi-layer forest communities were nearly eliminated from the Northern Glaciated Mountains ERU between historical and current periods. Conversely, three communities (late-seral subalpine single-layer forest, mid-seral montane forest, and upland woodland) increased by more than 100 percent.

Successionally, forest communities have transitioned to mid-seral forests within the Northern Glaciated Mountains ERU. With the exception of the late-seral subalpine single-layer forest (which increased), all late-seral forest communities declined by more than 90 percent (table 3.151). Over all, the areal extent of late-seral forest communities declined from 29 to 3 percent of the Northern Glaciated Mountains ERU. Conversely, ecologically significant increases were detected for all mid-seral forest communities, which in total, encompassed approximately 34 percent more land area of the ERU in the current period than in the historical period. Thus, mid-seral forest communities increased at the expense of early- and late-seral forest communities.

Although the upland woodland community increased by more than 400 percent, the change was not ecologically significant (table 3.151). Conversely, the areal increases of the current period exotic herbland and urban communities, which occurred at levels well above their historical ranges, were also not ecologically significant.

The Northern Glaciated Mountains ERU was dominated by transitions toward more homogeneous mid-seral forests. The nearly one-third of the ERU which was converted to the mid-seral montane forest community, originated mostly from the early-seral montane forest and late-seral montane multi-layer forest communities (table 3.152, Jones 1996). Large-diameter trees were removed from late-seral montane forest communities, while younger forests developed more complex structures. The 91 percent areal decline of the late-seral montane multi-layer forest community was dominated by transitions to mid-seral montane (72%) or early-seral montane forest (16%) communities. Almost all of the late-seral subalpine multi-layer forest community type was similarly converted to younger forest communities. Single-layer lower montane and montane forest communities were nearly eliminated as a result of conversions to mid-seral or early-seral communities. Agricultural conversions dominated the transitions of rangeland communities, affecting 12 percent of the Northern Glaciated Mountains ERU. Most of the agricultural development occurred within the upland herbland and upland shrubland communities.

Northern Great Basin ERU

The richness of terrestrial communities increased from 16 to 18 types between the historical and current periods (table 3.153). The two additional communities detected in the current period included two anthropogenic types (agricultural and exotic herbland).

Ecologically significant class and ERU trends were detected for seven and four communities, respectively (table 3.153). Most of the early-seral lower montane forest and upland herbland communities (89 and 55%, respectively) were converted to other communities between the historical and current periods. Conversely, the areal extent of four communities (late-seral montane multi-layer forest, late-seral montane single-layer forest, late-seral subalpine multi-layer forest, and upland woodland) increased by more than 200 percent. However, of these communities, only the increasing trends of the late-seral montane multi-layer forest

[3]Proportion of ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

and upland woodland community types were ecologically significant relative to the Northern Great Basin ERU.

The areal extent of 5 of 19 current period terrestrial communities occurred within their median historical ranges (alpine, late-seral lower montane single-layer forest, late-seral subalpine multi-layer forest, upland shrubland, and water). Thus, although the late-seral lower montane single-layer forest and late-seral subalpine multi-layer forest experienced substantial class changes, these changes were not ecologically significant (that is, they appeared to occur within the HRV for these types). Similarly, the decline of the upland shrubland community across 7 percent of the ERU was within the HRV.

Landscape changes in terrestrial communities within the Northern Great Basin ERU were dominated by the areal decline of the upland shrubland community (table 3.154, Jones 1996). Agricultural development, exotic plant invasions, and the encroachment of the upland woodland community were the primary causal factors in the decline of the upland shrubland community. Less

Terrestrial Community		
Historical Period[2]	**Current Period**	**Proportion of ERU Area (%)[3]**
Upland Shrubland	Agricultural	2.6
Upland Shrubland	Exotic Herbland	1.7
Upland Shrubland	Upland Woodland	1.6

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]*Historical Period = circa 1850 to 1900; Current Period = circa 1991.*

[3]Proportion of ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

extensive declines were detected in the upland herbland and late-seral lower montane single-layer forest communities. Sixty-four percent of the areal decline of the upland herbland community was attributable to the encroachment of the upland woodland and lower montane forest communities, and to a lesser degree, to conversion to the upland shrubland, exotic herbland, or agricultural community types.

Successional processes were largely responsible for the loss of 25 percent of the late-seral lower montane single-layer forest community. The areal decline of the late-seral lower montane single-layer forest type was dominated by the development of the structurally more complex late-seral montane multi-layer forest and late-seral lower montane multi-layer forest communities. Similarly, the increase of the late-seral montane multi-layer forest type was primarily a result of the successional development of early- and mid-seral montane forest, as well as the late-seral lower montane single-layer forest communities.

As a group, late-seral forest communities increased from 5 to 7 percent of the Northern Great Basin ERU (table 3.153). The net increase was dominated by a significant increase in late-seral multi-layer forest types as late-seral single-layer forest types declined. Although the area of early-seral and mid-seral forest communities declined, the ERU trends were not significant.

Owyhee Uplands ERU

The richness of terrestrial communities in the Owyhee Uplands ERU increased from 13 to 20 types between the historical and current periods (table 3.155). The seven additional communities included three anthropogenic types (agricultural, exotic herbland, and urban) and three subalpine forest communities. However, of the seven, only the agricultural and exotic herbland communities composed a substantial proportion of the Owyhee Uplands ERU during the current period.

Ecologically significant class and ERU trends were detected for eight and four communities, respectively (table 3.155). The dominant changes affecting the composition of the Owyhee Uplands ERU included agricultural conversion and decline of the upland shrubland community across 12 and 13 percent of the landscape, respectively. Six of the 20 community types (alpine, early-seral montane forest, late-seral montane multi-layer forest, mid-seral subalpine forest, upland shrubland, and water) occurred within their median historical ranges during the current period. Although substantial departures were documented for the early-seral subalpine forest, late-seral subalpine multi-layer forest, late-seral subalpine single-layer forest, and urban communities, their departures were not ecologically significant.

Table 3.156—Dominant transitions[1] of terrestrial communities within the Owyhee Uplands Ecological Reporting Unit (ERU).

Terrestrial Community		
Historical Period[2]	**Current Period**	**Proportion of ERU Area (%)[3]**
Upland Herbland	Upland Shrubland	2.9
Upland Shrubland	Agricultural	9.7
Upland Shrubland	Exotic Herbland	2.6
Upland Shrubland	Upland Herbland	2.4
Upland Shrubland	Upland Woodland	1.1

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

Terrestrial community transitions within the Owyhee Uplands ERU were dominated by the agricultural conversion of 12 percent of the area, most of which occurred within the upland shrubland community (table 3.156, Jones 1996). Lesser declines in the upland shrubland community were attributable to the invasion of exotic plants, and the encroachment of the upland woodland community (primarily western juniper). Upland shrublands and upland herblands transitioned to each other from the historical to the current period, but the net transition reflected a conversion of upland herbland to upland shrubland. The areal decline of the late-seral lower montane single-layer forest community was largely attributable to disturbances that resulted in their conversion to early- and mid-seral montane forest communities. In addition, the areal decline of the early-seral lower montane forest community was a result of transitions of montane and lower montane forest communities or early-seral montane forest community to mid-seral communities.

Snake Headwaters ERU

The richness of terrestrial communities increased between the historical and current periods (table 3.157). Three anthropogenic types occurred in the current period, but not in the historical period. Conversely, the early-seral lower montane forest and late-seral lower montane multi-layer forest communities occurred historically, but not during the current period.

Of the 21 community types detected within the Snake Headwaters ERU, ecologically significant trends relative to class and ERU were observed for 11 and 9 communities, respectively. Areal declines in the late-seral montane multi-layer forest, late-seral subalpine multi-layer forest, upland shrubland, and upland woodland communities exceeded 75 percent between historical and current periods. Conversely, the early-seral subalpine forest and late-seral lower montane single-layer forest communities increased by more than 1,000 percent.

The areal extent of 5 of the 21 terrestrial community types occurred within their median historical ranges during the current period (alpine, early-seral montane forest, late-seral lower montane single-layer forest, rock/barren, and water; table 3.157). The substantial departures that occurred with the mid-seral lower montane forest and urban communities were not ecologically significant.

The decline of the upland shrubland community type across about 13 percent of the ERU represented the most extensive landscape change in the

Table 3.157—Changes of broad-scale terrestrial communities between historical and current periods within the Snake Headwaters Ecological Reporting Unit (ERU).

[1]Historical Area = circa 1850 to 1900 (initiated model simulation); Historical Minimum = minimum value from 400-year simulation output; Historical Maximum = maximum value from 400-year simulation output; Current Area = circa 1991.

[2]Class change = percent change relative to the terrestrial community.

[3]ERU change = percent change of the ERU attributable to the terrestrial community change.

[4]Departure class = index of current areal extent of broad-scale cover types with respect to their historical ranges. Classes: (1) is < historical minimum; (2) is ≥ historical minimum but < median 75% historical range; (3) is within median 75% historical range; (4) is >median 75% historical range and ≤ historical maximum; (5) is > historical maximum.

[5]NA = Not Applicable; the terrestrial community did not exist during the historical period.

[6]T = Trace amount ≤ 0.01%.

*Ecologically significant changes.

Snake Headwaters ERU. Nearly one-half of the decline of the upland shrubland community was a result of agricultural development (table 3.158, Jones 1996). The remainder of the decline was attributable primarily to the encroachment of the mid-seral montane forest community. Changes in forested communities were dominated by transitions toward younger, less structurally complex communities. A 92 percent areal decline of the late-seral montane multi-layer forest community was dominated by changes to early- and mid-seral montane forest communities, and to a lesser degree, to the mid-seral subalpine forest community. Likewise, the decline of 90 percent of the late-seral subalpine multi-layer forest community was a result of transitions to both early- and mid-seral subalpine forest, and early- and mid-seral montane forest communities.

The distribution of forest communities became more centered around middle-aged forests. As a whole, late-seral forest communities decreased from approximately 16 to 4 percent and mid-seral forests increased from 29 to 34 percent of the Snake Headwaters ERU (table 3.157).

Southern Cascades ERU

The richness of terrestrial communities within the Southern Cascades ERU increased by three anthropogenic communities (agricultural, exotic herbland, and urban) between the historical and current periods (table 3.159). During this time interval, ecologically significant class and ERU trends occurred for 9 and 10 communities, respectively. The trends of the late-seral montane single-layer forest and late-seral lower montane single-layer forest communities dominated the landscape changes that occurred across the Southern Cascades ERU. The late-seral montane single-layer forest community increased, whereas the late-seral lower montane single-layer forest community decreased across approximately 8 percent of the ERU.

Six of 21 communities occurred within their median historical ranges during the current period (alpine, early-seral montane forest, late-seral subalpine single-layer forest, upland woodland, rock/barren, and water; table 3.159). Although substantial areal changes occurred with the early-seral montane forest and late-seral subalpine single-layer forest communities, the changes were not ecologically significant. Similarly, although the current areal extent of the exotic herbland and urban communities occurred well above historical conditions, the increases were not ecologically significant.

Terrestrial community transitions within the Southern Cascades ERU were dominated by increases in both late-seral montane single-layer forest and late-seral montane multi-layer forest communities that affected nearly 9 and 8 percent of the ERU, respectively (table 3.160, Jones 1996). The increase of the late-seral montane single-layer forest community type was derived predominantly from the late-seral lower montane single-layer forest, mid-seral montane forest, and mid-seral lower montane forest communities, whereas the increase in the late-seral montane multi-layer forest community type occurred at the expense of the mid-seral subalpine forest, and early-, and mid-seral montane forest communities. The 8.5 percent areal decline of the late-seral lower montane single-layer forest community was primarily attributable to a transition to the mid-seral lower montane forest type. Successional processes were largely responsible for the observed decreases in mid-seral subalpine forest and mid-seral montane forest communities. Nearly one-half of the mid-seral subalpine forest community changed into the late-seral montane multi-layer forest community, although 24 percent was converted into the early-seral montane forest community. The decline of the mid-seral montane forest community was dominated by an increase of the late-seral montane multi-layer forest community. In rangeland communities, agricultural conversion was the greatest causal factor in the detected loss of upland shrubland and upland herbland from the historical to the current period.

Table 3.158—Dominant transitions[1] of terrestrial communities within the Snake Headwaters Ecological Reporting Unit (ERU).

Terrestrial Community		
Historical Period[2]	**Current Period**	**Proportion of ERU Area (%)[3]**
Early-seral Montane Forest	Mid-seral Montane Forest	5.9
Late-seral Montane Multi-layer Forest	Early-seral Montane Forest	1.6

Upland Shrubland	Mid-seral Montane Forest	4.0
Upland Woodland	Upland Herbland	1.0

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

As a group, late-seral forest communities increased from approximately 30 to 35 percent of the Southern Cascades ERU (table 3.159). The net change of late-seral forest communities was dominated by the increase of multi-layer communities, as the decline of single-layer communities was insignificant. The areal extent of early-seral forest communities also increased, whereas the area of mid-seral forest communities decreased.

Upper Clark Fork ERU

The richness of terrestrial communities increased from 18 to 19 community types in the Upper Clark Fork ERU between the historical and current periods (table 3.161). During this time interval, three anthropogenic communities (agricultural, exotic herbland, and urban) were added, while two communities (late-seral montane single-layer forest and late-seral lower montane single-layer forest) were eliminated.

Of the 21 communities detected within the Upper Clark Fork ERU, the areal extent of only the alpine, rock/barren, and water community types occurred within their median historical ranges during the current period (table 3.161). The majority of the terrestrial communities had ecologically significant class (62%) and ERU trends (62%). Seven of 9 communities that had significantly declining class trends decreased by more than 80 percent.

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

With the exception of the late-seral subalpine single-layer forest community, all of the late-seral forest communities declined by more than 90 percent (table 3.161). As a group, the areal extent of late-seral forest communities declined from approximately 15 to 1 percent of the Upper Clark Fork ERU. Conversely, the mid-seral lower montane forest and mid-seral subalpine forest communities increased by more than 175 percent.

The structures of broad-scale forest communities became more homogenized between the historical and current periods. A net loss of early- and late-seral forest communities affected 7 and 15 percent of the ERU, respectively. Conversely, the net increase of mid-seral forest communities encompassed nearly 28 percent of the Upper Clark Fork ERU.

The decline of the upland herbland community was the most extensive regional change in the Upper Clark Fork ERU from the historical to the current period (table 3.161). Agricultural conversion and encroaching lower montane and montane forest communities were each responsible for nearly a 33 percent areal reduction of the upland herbland community type (table 3.162, Jones 1996). Net transitions to mid-seral subalpine, mid-seral lower montane, and mid-seral montane forest communities were somewhat less extensive, occurring on approximately 7, 11, and 6 percent of the ERU, respectively. The areal extent of the mid-seral lower montane forest community increased by the encroachment into the upland herbland community, and the loss of large-diameter trees from the late-seral lower montane single-layer forest community. The mid-seral subalpine forest community increased via transitions from early- and mid-seral montane forest communities. The increase of the mid-seral montane forest community type was derived predominantly from the successional development of the early-seral montane forest community, as well as from the loss of large-diameter trees in the late-seral montane multi-layer forest community.

Upper Klamath ERU

The richness of terrestrial communities increased from 18 to 20 communities between the historical and current periods (table 3.163). During this time interval, three anthropogenic communities (agricultural, exotic herbland, and urban) developed, while the mid-seral subalpine community was eliminated.

Of the 21 terrestrial communities detected within the Upper Klamath ERU, 4 types (alpine, late-seral lower montane single-layer forest, rock/barren, and water) occurred within their median historical ranges during the current period (table 3.163). Ecologically significant class and ERU trends were detected for 12 and 11 terrestrial communities, respectively. The early-seral lower montane forest community was virtually eliminated, while the areal extent of three other communities (early-seral subalpine forest, upland herbland, and upland shrubland) declined by at least 75 percent. Conversely, the areal extent of the late-seral montane single-layer forest, late-seral montane multi-layer forest, and upland woodland communities increased greatly. Overall, forest communities aged, as we detected net areal declines of early-seral (2%) and mid-seral (18%) forest communities, while late-seral forest communities covered an additional 27 percent of the Upper Klamath ERU between the historical and current periods.

Although the late-seral lower montane single-layer forest community declined across 3 percent of the Upper Klamath ERU, its areal extent during the current period continued to exist within its median historical range (table 3.163). Consequently, the change was not ecologically significant. Similarly, the substantial departures that were detected with the exotic herbland, late-seral subalpine single-layer forest, and urban communities were also not ecologically significant, as none of these communities constituted substantial proportions of the Upper Klamath ERU.

Table 3.161—Changes of broad-scale terrestrial communities between historical and current periods within the Upper Clark Fork Ecological Reporting Unit (ERU).

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

Terrestrial community transitions within the Upper Klamath ERU were dominated by the progression of young to older forests, and the development of more complex structures (for example, single-layer to multi-layer stands). Species composition also changed substantially. The increase of late-seral montane forest communities was dominated by the conversion of the lower montane forest community types (table 3.164, Jones 1996). More specifically, the increase of the late-seral montane multi-layer forest community was derived largely from late-seral lower montane single-layer forest and mid-seral lower montane forest communities, and to a lesser degree, by the development of the mid-seral montane forest community. Similarly, the increase of the late-seral montane single-layer forest community was dominated by the development of mid-seral lower montane forest and late-seral lower montane single-layer forest communities. More complex structures also developed in lower montane forest communities.

The rangeland communities (upland herbland and upland shrubland) transitioned predominantly to agricultural, upland woodland, or lower montane forest communities. Of the 93 percent decline of the upland herbland community, 34 percent was attributable to transition to lower montane forest communities, 32 percent to transition to agricultural communities, and 19 percent to transition to upland woodland communities.

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

Upper Snake ERU

The richness of terrestrial communities declined from 16 to 14 communities between historical and current periods (table 3.165). Although three anthropogenic communities (agricultural, exotic herbland, and urban) developed during this time interval, five endemic community types (early-seral lower montane forest, early-seral subalpine forest, late-seral montane multi-layer forest, late-seral lower montane multi-layer forest, and late-seral subalpine multi-layer forest) were eliminated. Ecologically significant class and ERU trends occurred between historical and current periods for 10 and 4 communities, respectively (table 3.165). Although five community types were not detected in the current period, their loss represented only a minor compositional change in the Upper Snake ERU. Changes of two communities dominated the compositional alteration of the ERU. Approximately 33 percent of the landscape transitioned to the agricultural community, whereas the ERU extent of the upland shrubland community declined 46 percent.

Table 3.166—Dominant transitions[1] of terrestrial communities within the Upper Snake Ecological Reporting Unit.

Terrestrial Community		
Historical Period[2]	Current Period	Proportion of ERU Area (%)[3]
Upland Herbland	Agricultural	4.5
Upland Shrubland	Agricultural	31.8
Upland Shrubland	Exotic Herbland	7.3
Upland Shrubland	Upland Herbland	5.9
Upland Shrubland	Upland Woodland	1.6

[1]Dominant transitions affected at least 1 percent of the landscape.

[2]Historical Period = circa 1850 to 1900; Current Period = circa 1991.

[3]Proportion of ERU Area (percent) = proportion of landscape affected; the area of the ERU in which a terrestrial community changed into another terrestrial community.

Of the 19 terrestrial communities that were detected within the Upper Snake ERU, 5 (alpine, late-seral montane single-layer forest, late-seral lower montane single-layer forest, mid-seral montane forest, and water) occurred within their median historical range during the current period (table 3.165). Three of these communities had substantial class trends: a 55 percent decline for late-seral montane single-layer forest, a 73 percent increase for late-seral lower montane single-layer forest, and a 118 percent increase for mid-seral montane forest.

Terrestrial community transitions within the Upper Snake ERU were dominated by the 46 percent decline of the upland shrubland community, and the conversion of a large proportion (33%) of the ERU to agriculture (table 3.166; Jones 1996). In addition to agricultural conversion, the upland shrubland community was also extensively invaded by exotics.

Terrestrial communities discussion

As expected, the changes of broad-scale terrestrial community types did not occur uniformly throughout the Basin. Because of its geographic extent and variation in geologic history and climatic regimes, the diversity of biophysical environments within the Basin is inherently complex (see the Biophysical, Chapter 2 of this document for further details). Consequently, so too are the variations of disturbance regimes (both natural and human-influenced)(Long and others 1996), and subsequent composition of potential vegetation types (Hann and others 1997). However, the vegetation changes that we observed within the Upper Klamath ERU were very dissimilar to those observed for the Basin. Among the 13 ERUs, the greatest variation in trends of a single community type occurred with the mid-seral subalpine forest community. The current area of this community occurred well below its median historical range within four ERUs, well above its median historical range in eight ERUs, and occurred within its median historical range in one ERU.

Other terrestrial communities having a relatively wide variation of departure indices among the ERUs included the early-seral montane forest, early-seral subalpine forest, late-seral multi-layer forest, late-seral montane single-layer forest, and upland woodland community types. Conversely, there was virtually no variation of departure indices of nine terrestrial communities (agricultural, alpine, early-seral lower montane forest, exotic herbland, mid-seral lower montane forest, rock/barren, upland herbland, urban, and water) among the 13 ERUs and the Basin.

In Basin rangeland communities, the substantial loss of the upland herbland and upland shrubland community types, attributable to the transition to agriculture, was detected in all ERUs except the Lower Clark Fork. A substantial extent of upland shrubland and upland herbland also transitioned to upland woodland. This was typically attributable to fire suppression, but was often accelerated by excessive livestock grazing pressure. This transition was most prevalent in the Blue Mountains, Columbia Plateau, Northern Glaciated Mountains, Northern Great Basin, Owyhee Uplands, Upper Klamath, and Upper Snake ERUs, specifically in areas characterized by a mixture of forest and rangeland communities with extensive ecotonal areas, or the presence of a historical woodland component.

Over the last 100 to 150 years, disturbances within forest communities favored the development of mid-seral forest communities at the expense of both late-seral forest, and to a lesser degree, early-seral forest communities. A net increase of mid-seral forest communities, and net declines of early- and late-seral forest communities were detected Basin-wide, as well as within the Lower Clark Fork, Upper Clark Fork, and Northern Glaciated Mountains ERUs. These changes were most likely a consequence of both fire suppression and timber harvest activities throughout the Basin. Timber harvest activities reduced the areal extent of late-seral forest communities, while fire suppression activities limited the recruitment of early-seral forest communities. Apparently, harvest activities that resulted in early-seral forest communities did not keep pace with the successional rates of change in younger stands. Consequently, the middle-age forests dominated the distribution of seral communities within current period forested environments more than they had historically.

Over all, the relative magnitude of change we detected in the lower montane forest communities was greater than that observed within the subalpine forest communities. Natural disturbance frequencies within the lower montane communities were typically greater than those of subalpine environments (Long and others 1996). Successional rates of change occurred more slowly in subalpine environments. Consequently, the effects of altering disturbance regimes accrued much faster in lower montane environments. In addition, human settlement patterns tended to concentrate in lower-elevation, more hospitable environments. Thus, the direct and indirect effects of human occupancy also tended to be oriented around lower montane communities. In the Basin, agricultural development, livestock grazing, fire suppression, and timber harvest have all had significantly greater impacts over relatively longer time periods on lower montane forests than on subalpine forests.

We were able to make some comparisons at the ERU level of our broad-scale vegetation trends to the mid-scale vegetation trends reported by Hessburg and others (1996a). Classifications used in the mid-scale assessment that approximated some of our terrestrial communities or our further aggregation of terrestrial communities, included three physiognomic types (woodland, shrubland, and herbland), the ponderosa pine cover type, and three forest structural classes (stand initiation, old multi-story, and old single-story). These mid-scale classifications were comparable to (1) our upland woodland, upland shrubland, and upland herbland terrestrial communities, and (2) our aggregations of four lower montane forest communities, three early-seral forest communities, three late-seral multi-layer forest communities, and three late-seral single-layer forest communities. As with our analyses of cover types, there were some discrepancies between the two data sets. Again, considering that the two analyses were conducted at different resolutions and that trends were assessed across different time periods, the conclusions were remarkably similar.

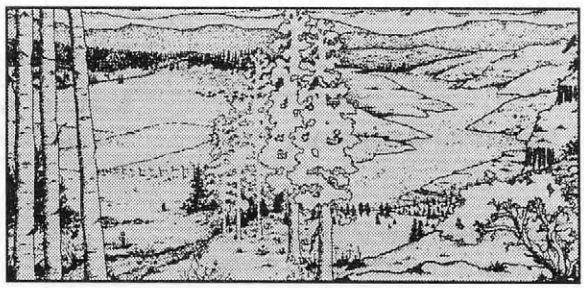
The most frequent discrepancies involved vegetation communities for which the broad-scale analysis generated significant trends, whereas the mid-scale assessment did not. These discrepancies commonly occurred with Hessburg and others' (1996a) forest structural types within the Lower Clark Fork, Upper Clark Fork and Northern Glaciated

Mountains ERUs, and the woodland and shrubland physiognomic types within the Northern Cascades, Northern Glaciated Mountains, Upper Clark Fork, and Upper Klamath ERUs. With respect to forest structural types, we likely detected trends because our assessment period included the occurrence of the expansive wildfires that occurred throughout the Lower Clark Fork, Upper Clark Fork, and Northern Glaciated Mountains ERUs during the early-1900s—prior to the assessment period used in the mid-scale assessment.

The apparent discrepancies with the woodland and shrubland physiognomic types might have been attributable to differences in the resolution and/or the time periods for which trends were assessed. Conflicting trends (that is, trends in which the broad-scale and mid-scale assessments detected opposite tendencies) most commonly involved the upland herbland terrestrial community and herbland physiognomic types. We detected significant declines of the upland herbland community within 12 of 13 ERUs, whereas Hessburg and others (1996a) detected positive trends of the herbland physiognomic type within five ERUs, and no significant change of this type within four ERUs.

We speculate that these differences in trend should not have been unexpected, however, because (1) the mid-scale herbland physiognomic types included exotics and irrigated pasture cover types, whereas the broad-scale upland herbland community excluded these cover types, and (2) early literature pertinent to the Basin (for example, Griffiths 1902) indicated that the herbland component was already in low vigor by the turn of the century, and attributed the condition to excessive livestock grazing pressure. Our speculation was that appreciable upland herbland had transitioned to other communities prior to the mid-scale analysis assessment period. Therefore, the baseline status of the herbland community for the mid-scale analysis was different than for the broad-scale analysis. Conflicting trends also occurred for the old multistory structural class and the late-seral multi-layer forest communities in the Blue Mountains ERU; the stand initiation structural class and early-seral forest communities in the Central Idaho Mountains ERU; the woodland physiognomic type and the upland woodland community in the Snake Headwaters ERU; and the ponderosa pine cover type and lower montane forest communities in the Southern Cascades and Upper Clark Fork ERUs. We were unable to establish rational hypotheses regarding the factors responsible for these conflicting trends.

We commonly detected substantial trends of terrestrial communities between historical and current periods that apparently fell within the expected range of historical variation. Thus, as we observed in our analysis of cover types, major compositional changes of at least some broad-scale communities were apparently the norm, rather than the exception. Only by grounding observed changes to some historical range of conditions, could the ecological consequences of change be fully understood.



For our analysis of broad-scale terrestrial communities, we chose to summarize broad-scale community composition and trends at the ERU and Basin levels. As stated in the previous "Regional Cover Type Trends" subsection, we do not imply that trends we observed would occur at other scales. In fact, we detected spatial variation of vegetation changes at the ERU level, which were not consistent with those observed for the Basin as a whole. Our transition analyses indicate that trends for a specific terrestrial community could differ appreciably within and amongst ERUs. This was because the pixels of a specific terrestrial community could change in different ways from the historical to the current period (that is, the pixels could stay the same or convert into another terrestrial community). Consequently, the trends observed at the ERU level should not be interpreted as meaning a consistent trend occurred everywhere throughout the ERU where a particular community exists. Given this level of variability for specific terrestrial communities at the ERU level, we expect that trends for specific terrestrial communities at a finer scale would likewise be variable and might be inconsistent with ERU trends.

REGIONAL AND ECOLOGICAL REPORTING UNIT BROAD-SCALE LANDSCAPE TRENDS

Regional Broad-Scale Landscape Departure

Eight of 12 terrestrial community groups (early-seral lower montane forest, late-seral lower montane forest, early-seral montane forest, late-seral montane forest, mid-seral subalpine forest, late-seral subalpine forest, upland herbland, and upland shrubland) were below their historical range (that is, Departure Class 1) in a high percentage of the subbasins in which they existed. The remaining four terrestrial community groups (mid-seral lower montane forest, mid-seral montane forest, early-seral subalpine forest, and upland woodland) were above their historical range (that is, Departure Class 5) in a high percentage of the subbasins in which they existed (tables 3.7, 3.9, and 3.167). The average frequency of subbasin membership in Class 1 and Class 5 departures was 48 and 28 percent, respectively. During the current period, community groups existed within their 75 percent median historical range (that is, Departure Class 3) in few subbasins. The average frequency of subbasins containing community groups within their 75 percent median historical range was only 14 percent. The greatest deviation from historical ranges occurred in the early- and late-seral lower montane forests — nearly 80 percent of the subbasins contained areas of these community groups at levels below their historical ranges (that is, Class 1 departures).

Early-seral Lower Montane Forest

Nearly all the subbasins (94%) that contained the early-seral lower montane forest terrestrial community group showed extents that were below their median 75 percent historical range (table 3.167, map 3.47). However, the Northern Cascades ERU was the exception in that it was largely dominated by subbasins in which the areal extent of the early-seral lower montane forest community group was within or above its median historical range. Five isolated subbasins (or a frequency of 4%) contained this community group within its 75 percent median historical range. These subbasins were in the Northern Cascades, Northern Glaciated Mountains, Columbia Plateau, and Central Idaho Mountains ERUs (table 3.168; map 3.47).

Within the Basin, five patches of eight subbasins (7 % of the subbasins) had the early-seral lower montane forest community group within or above its median historical range (table 3.169; map 3.47). Two of these patches existed as isolated individual subbasins; one each in the Blue Mountains and Central Idaho Mountains ERUs. The other three patches were clustered in the northwest portion of the Basin, two occurred in the Northern Cascades ERU, and one on the western edge of the Northern Glaciated Mountains ERU. The largest patch (three subbasins) occurred within the Northern Cascades ERU. Consequently, species whose fitness is closely correlated with the areal extent of the early-seral lower montane forest community group are likely doing well in the northwestern portion of the Basin relative to other areas within the Basin.

Table 3.167—Summary of subbasin frequency distribution by current terrestrial community group departures.

[2]*Departure class = index of current areal extent of broad-scale cover types with respect to their historical ranges.* Classes: (1) is < historical minimum; (2) is ≥ historical minimum but < median 75% historical range; (3) is within median 75% historical range; (4) is >median 75% historical range and ≤ historical maximum; (5) is > historical maximum.

[3]Average subbasin frequency distribution across 12 terrestrial community group departure classes.

[4]Not Applicable.

Mid-seral Lower Montane Forest

The Basin was dominated by subbasins (61%) in which the mid-seral lower montane community group occurred above its 75 percent median historical range (table 3.167, map 3.48). Subbasins having Class 5 departures were located in Washington, Oregon, Montana, and Idaho (for example: the Northern Cascades, Northern Glaciated Mountains, Columbia Plateau, Blue Mountains, and portions of the Southern Cascades, Northern Great Basin, and Upper Klamath ERUs in Oregon and Washington; the Upper Clark Fork ERU and several adjacent subbasins within the Lower Clark Fork and Northern Glaciated Mountains ERUs in Montana; and the Central Idaho Mountains ERU in Idaho). However, the Upper Klamath ERU, and the Idaho and northwestern Montana portions of the Northern Glaciated Mountains and Lower Clark Fork ERUs were dominated by subbasins classified as Class 1 departures. Nine patches of 13 subbasins (10% of the subbasins) contained the mid-seral lower montane forest community group within its median historical range (table 3.168). Most of these patches were clustered in the western half of the Central Idaho Mountains ERU, and a few adjacent subbasins of the Blue Mountains and Owyhee Uplands ERUs. The patches contained one to three subbasins (median = 1.0 subbasin) each.

Map 3.47—Broad-scale habitat departure of the early-seral lower montane forest terrestrial community group. The term "terrestrial community type" used in this map title is actually "terrestrial community group"; terrestrial community types were aggregated into groups for analysis of broadscale habitat departures.

Map 3.48—Broad-scale habitat departure of the mid-seral lower montane forest terrestrial community group. The term "terrestrial community type" used in this map title is actually "terrestrial community group"; terrestrial community types were aggregated into groups for analysis of broadscale habitat departures.

Table 3.168—Fragmentation indices of terrestrial community groups occurring within subbasins at a level within their median historical ranges; summation of Departure Class 3.

	Frequency of Subbasins[1] (%)	Number of Patches	Median Patch Size[2]	Maximum Patch Size
Early-seral Lower Montane Forest	4	5	1.0	1
Late-seral Lower Montane Forest	7	3	2.0	6
Mid-seral Lower Montane Forest	10	9	1.0	3
Early-seral Montane Forest	18	17	1.0	5
Late-seral Montane Forest	9	7	2.0	3
Mid-seral Montane Forest	19	14	1.0	7
Early-seral Subalpine Forest	20	6	1.5	5
Late-seral Subalpine Forest	12	4	1.5	7
Mid-seral Subalpine Forest	20	10	1.5	5
Upland Herbland	12	13	1.0	4
Upland Shrubland	22	9	2.0	11
Upland Woodland	13	9	1.0	4

[1]Frequency of Subbasins = the percentage of those subbasins having at least a 1 percent historical or current period composition of a terrestrial community group and in which that community group occurred within its median historical range.
[2]Patch Size = count of subbasins within a patch.

There were 2 patches of 77 subbasins (71% of the subbasins) in which the mid-seral lower montane forest community occurred within or above its median historical range (table 3.169; map 3.48). One patch was relatively small (2 subbasins) and isolated in the southern portion of the Upper Klamath ERU. The second patch was large (75 subbasins), and although it contained some gaps, the subbasins were well distributed throughout the rest of the Basin. Consequently, species whose fitness is closely correlated with the areal extent of the mid-seral lower montane forest community group are likely doing well across most of the Basin. However, as stated previously, there could be areas within the Basin where the persistence of these species might be in serious jeopardy (for example, the northern Upper Klamath ERU, the western portion of the Northern Great Basin ERU, much of the eastern portion of the Northern Glaciated Mountains ERU, the Lower Clark Fork ERU, and the western portion of the Central Idaho Mountains ERU).

Late-seral Lower Montane Forest

The Basin was dominated by subbasins (78%) in which the late-seral lower montane forest community group existed below its median historical range (table 3.167, map 3.49). Notable exceptions included the Upper Klamath ERU and adjacent portions of the Northern Great Basin ERU. The Upper Klamath ERU and two adjacent subbasins within the Northern Great Basin ERU formed a relatively large contiguous patch of subbasins that contained this community group above its historical range. Three isolated and relatively small (patch size range = 1 to 6 subbasins, median patch size = 2 subbasins; table 3.168) patches of subbasins that had this community group within their median historical range occurred in central Oregon, central Idaho, and southeastern Idaho.

The persistence of those species that rely heavily upon the areal extent of the late-seral lower montane forest community group are likely at risk across most of the Basin. There were only 3

relatively isolated patches of 17 subbasins in which this community group existed within or above its median historical range, and consequently, where these species might be doing relatively well (table 3.169; map 3.49). The largest of these patches (14 subbasins) was located within the Upper Klamath ERU, southern portions of the Southern Cascades and Columbia Plateau ERUs, and southwestern portions of the Northern Great Basin ERU. The two other patches were relatively small (one to two subbasins), and were isolated within the center of the Central Idaho Mountains ERU, and the Upper Snake and Snake Headwaters ERUs.

Early-seral Montane Forest

Although the Basin was dominated by subbasins (51%) in which the early-seral montane forest community group occurred below its median 75 percent historical range (table 3.167, map 3.50), large portions of the Northern Cascades, Southern Cascades, Blue Mountains, and Central Idaho Mountains ERUs were dominated by subbasins in which this community group occurred within or above its median historical range. Seventeen relatively small and isolated patches of 23 subbasins that contained this community group within its median historical range were distributed throughout the Basin (table 3.168; range of patch size = 1 to 5 subbasins; median patch size = 1.0 subbasin).

There were 12 patches of 69 subbasins widely distributed within most of the Basin in which the early-seral montane forest community group existed within or above its median historical range (table 3.169; map 3.50). Patch size of these areas ranged from 1 to 34 subbasins (median = 3.5 subbasins). The most extensive, contiguous patch spanned a large proportion of the Blue Mountains and Central Idaho Mountains ERUs. Relatively extensive patches (that is, at least four contiguous subbasins) also existed within the Northern Cascades, Southern Cascades, Northern Glaciated Mountains, Lower Clark Fork, and Snake Headwaters ERUs.

Mid-seral Montane Forest

Fifty-nine percent of the subbasins that had at least 1 percent of their area in mid-seral montane forest community group, contained that community above its 75 percent median historical range (table 3.167, map 3.51). However, large portions of the Southern Cascades, Upper Klamath, and Central Idaho Mountains ERUs were dominated by subbasins in which this community group existed below its median historical range. Twenty-five (19%) subbasins had this community group within its median historical range, and were distributed across the Basin in 14 patches ranging in size from 1 to 7 subbasins (table 3.168; median patch size = 1.0 subbasin). The largest of these patches occurred in the Columbia Plateau, Snake Headwaters, and Upper Snake ERUs.

Most (78%) of the subbasins that had substantial areas of the mid-seral montane forest community group contained areas of that community group at levels within or exceeding the median historical range (table 3.169; map 3.51). Six patches that comprised 103 subbasins, ranging in size from 1 to 95 subbasins (median = 1.5 subbasins), were widely distributed throughout all but the southwest portion of the Basin. With the exception of the Upper Klamath ERU, the most extensive patches occurred within portions of all ERUs. Species whose fitness is strongly correlated with the areal extent of the mid-seral montane forest community group should be doing well in all areas of the Basin, except within large areas of the Southern Cascades, Upper Klamath, Northern Great Basin, and Central Idaho Mountains ERUs.

Late-seral Montane Forest

The Basin was dominated by subbasins (63%) in which the late-seral montane forest community group occurred below its 75 percent median historical range (table 3.167, map 3.52). However, most of the subbasins in Oregon and many of those within the Central Idaho Mountains ERU contained areas of the late-seral montane forest

Table 3.169—Fragmentation indices of terrestrial community groups occurring within subbasins at a level within or above their median historical ranges; summation of Departure Classes 3, 4, and 5.

	Frequency of Subbasins[1] (%)	Number of Patches	Median Patch Size[2]	Maximum Patch Size
Early-seral Lower Montane Forest	7	5	1.0	3
Late-seral Lower Montane Forest	13	3	2.0	14
Mid-seral Lower Montane Forest	71	2	38.5	75
Early-seral Montane Forest	50	12	3.5	34
Late-seral Montane Forest	37	3	3.0	43

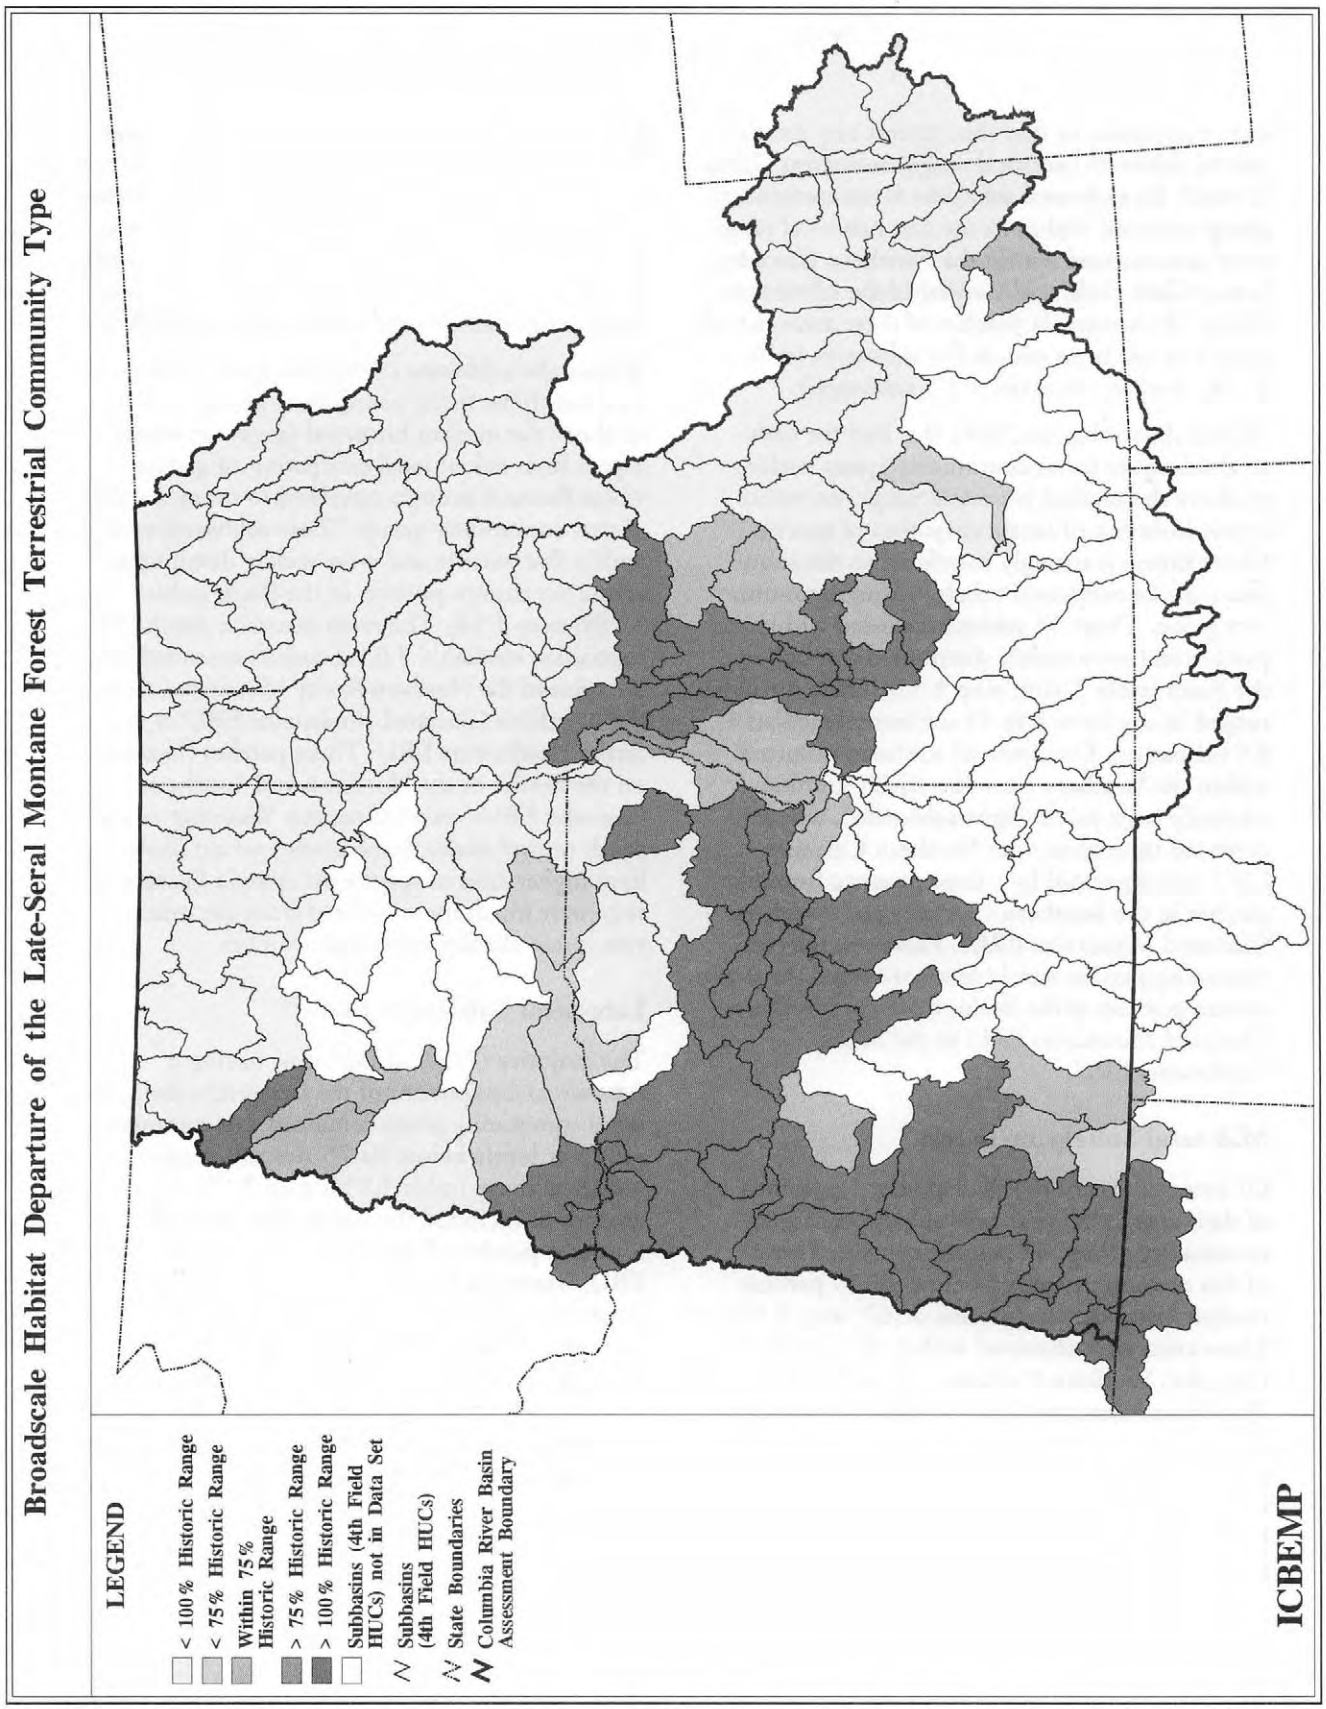
Upland Woodland	59	4	2.5	58

[1]Frequency of Subbasins = the percentage of those subbasins having at least a 1 percent historical or current composition of a terrestrial community group and in which that community group occurs within or above its median historical range.
[2]Patch Size = count of subbasins within a patch.

community group that exceeded their median historical ranges. Seven patches of subbasins (9%) that contained the late-seral montane forest community group within its median historical range were widely distributed across the Basin (table 3.168). The median patch size of these areas was two subbasins (range = 1 to 3 subbasins).

The distribution of subbasins in which the late-seral montane forest community group existed within or above its median historical range overlapped negligibly with that of the mid-seral montane forest community group (maps 3.51 and 3.52). There were 3 patches of 47 subbasins that contained areas of this community group within or above its median historical range (table 3.169). The largest patch (43 subbasins) spanned large areas of the Southern Cascades, Columbia Plateau, Upper Klamath, Blue Mountains, and Central Idaho Mountains ERUs (map 3.52). The other two patches were isolated within the Northern Cascades (three subbasins) and Snake Headwaters (one subbasin) ERUs. Consequently, we would expect productive populations of those species whose fitness is strongly correlated to the abundance of the late-seral montane forest community group to exist across most of the Oregon and central Idaho portions of the Basin. Conversely, we would anticipate a high risk of extirpation of these species across much of eastern Washington, northern and southeastern Idaho, and those portions of Montana and Wyoming within the Basin; these areas had poor late-seral montane forest community group representation.



Early-seral Subalpine Forest

Most (56%) subbasins that had at least 1 percent of the area in the early-seral subalpine forest community group contained areas of this community group exceeding the historical ranges (table 3.167, map 3.53). However, a large portion of the Northern Glaciated Mountains and Upper Clark Fork ERUs

Map 3.49—Broad-scale habitat departure of the late-seral lower montane forest terrestrial community group. The term "terrestrial community type" used in this map title is actually "terrestrial community group"; terrestrial community types were aggregated into groups for analysis of broadscale habitat departures.

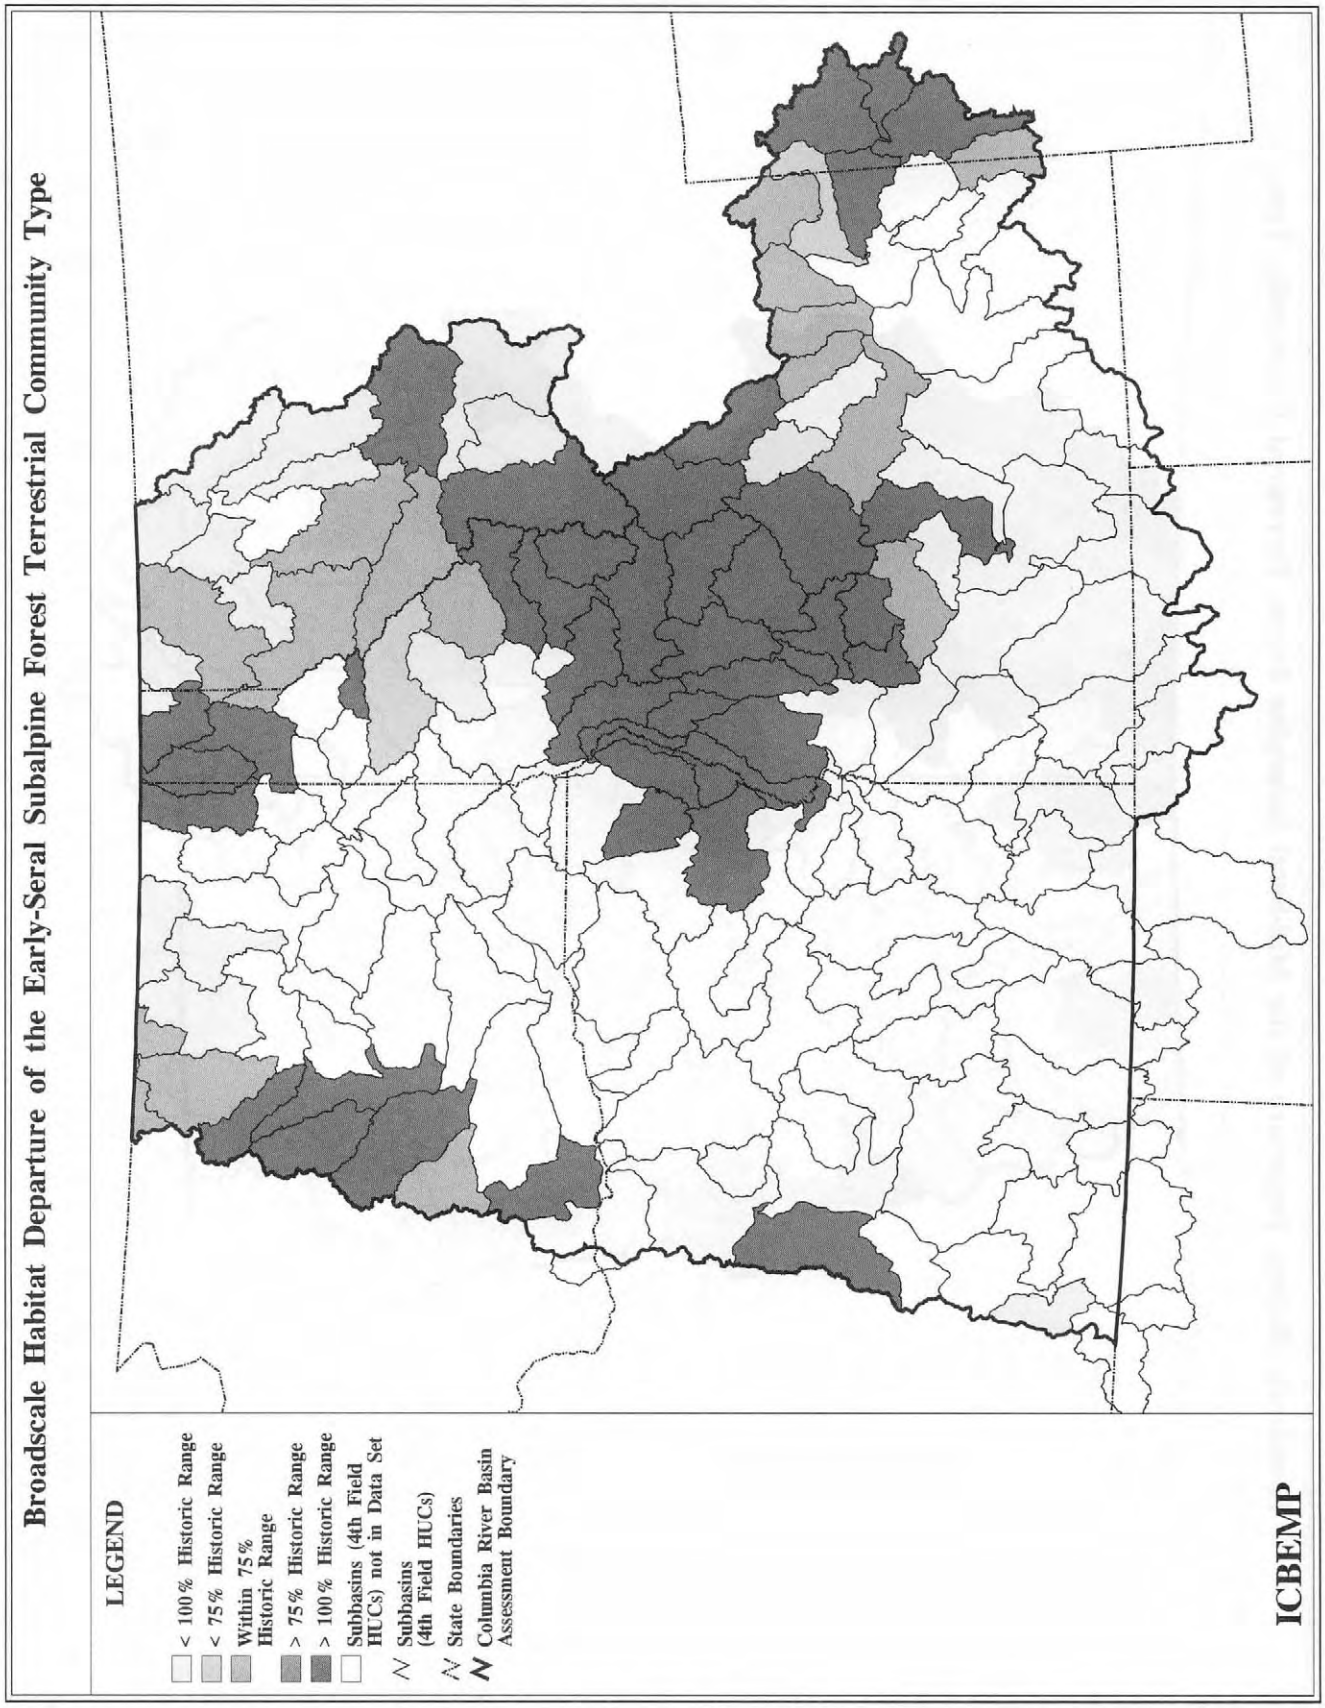
were exceptions, in that this community group existed below its historical range. Subbasins (20%) in which the early-seral subalpine forest community group occurred within its median historical range were concentrated within the Northern Cascades, Lower Clark Fork, and Central Idaho Mountains ERUs. There were six patches of these areas, which ranged in size from one to five subbasins (table 3.168; median patch size = 1.5 subbasins).

Within the subbasins (76%) that had the early-seral subalpine forest community group within or above the median historical range, we would expect little risk of local extirpation of species whose fitness is strongly correlated to the abundance of the early-seral subalpine forest community group. These 57 subbasins existed within 4 patches and were widely distributed throughout the Basin (table 3.169; map 3.53). These 4 patches ranged in size from 1 to 43 subbasins (median = 6.5 subbasins). One isolated subbasin occurred within the Southern Cascades ERU. Another relatively large patch (eight subbasins), which extended throughout the Northern Cascades ERU, was separated by a large distance from like patches in the Southern Cascades and Northern Glaciated Mountains ERUs. However, the two remaining patches nearly interconnected the entire eastern portion of the Basin, from the Northern Glaciated Mountains ERU to the Snake Headwaters ERU.

Mid-seral Subalpine Forest

Of those subbasins that had at least 1 percent of their area in the mid-seral subalpine forest community group, 47 percent contained areas of this community group below the 75 percent median historical range (table 3.167; map 3.54). These areas were clustered within the Northern Cascades, Southern Cascades, Upper Klamath, Blue Mountains, and Central Idaho Mountains ERUs. However, several relatively extensive areas of the Northern Glaciated Mountains, Lower Clark Fork, Upper Clark Fork, and Snake Headwaters ERUs were dominated by subbasins in which the mid-seral subalpine forest community group existed within or above its historical range. Ten patches of 18 subbasins existed that contained this community group within its median historical range (table 3.168). These patches ranged in size from one to five subbasins (median = 1.5 subbasins), the most extensive of which straddled the Northern Glaciated Mountains and Lower Clark Fork ERUs.

Within the subbasins (53%) that had the mid-seral subalpine forest community group within or above the median historical range, we would expect little risk of local extirpation of species whose fitness is strongly correlated to the availability of that community group. These subbasins existed within five patches and were widely distributed across the eastern portion of the Basin (table 3.169; map 3.54). The most extensive patch (39 subbasins; median = 3.0 subbasins) extended down the spine of the Northern Rocky Mountains, from the Northern Glaciated Mountains ERU to the Snake Headwaters ERU. Three patches (located on the border of the Northern and Southern Cascades ERUs, in northeastern Washington and south central Idaho, respectively) would likely have higher risks of species extirpation because they were much more isolated from the other two (more closely-connected) patches.



Late-seral Subalpine Forest

The majority (72%) of subbasins having a substantial component of the late-seral subalpine forest community group contained that community group at levels below its 75 percent median historical range (table 3.154; map 3.55). Notable exceptions included the Upper Klamath ERU and southern portion of the Central Idaho Mountains ERU, where the late-seral subalpine forest community group in most subbasins was within or exceeded its median historical range. Only 11 subbasins (12%) contained this community group at a level within its median historical range, and all but one of these were located within or immediately adjacent to the Central Idaho Mountains ERU.

Map 3.54—Broad-scale habitat departure of the mid-seral subalpine forest terrestrial community group. The term "terrestrial community type" used in this map title is actually "terrestrial community group"; terrestrial community types were aggregated into groups for analysis of broadscale habitat departures.

The most extensive, contiguous patch of subbasins that contained the late-seral subalpine forest community group within its median historical range was composed of seven subbasins (table 3.168; range = 1 to 7 subbasins; median patch size = 1.5 subbasins).

Species whose fitness is strongly correlated to the abundance of the late-seral subalpine forest group would have a high risk of local extirpation across most (72%) of the subbasins in which this community is a substantial component (table 3.169). However, two relatively large patches (6 and 21 subbasins, respectively) existed in which this community group occurred within or exceeded its median historical range (map 3.55). Although relatively extensive, these two patches were widely separated. The majority of one patch occurred in the Upper Klamath ERU, whereas the majority of the second patch occurred in the Central Idaho Mountains ERU.

Upland Herbland

The upland herbland community group occurred at a level below its 75 percent median historical range (table 3.167; map 3.56) in approximately 81 percent of the subbasins that had it as a substantial component. With the exception of a few subbasins, subbasins within the Oregon and Washington portions of the Basin had areas of the upland herbland community group below the median historical range. Although the Idaho and Montana areas were also dominated by subbasins in which the upland herbland community group existed below its median historical range, there were more extensive areas within the Central Idaho Mountains, Upper Snake, and Snake Headwaters ERUs, where this group existed within or above its median historical range. The 20 subbasins (12%) that had this community group within its median historical range were distributed within numerous (13) patches that were isolated and small in extent (table 3.168; patch size range = 1 to 4 subbasins; median patch size = 1.0 subbasin).

Within the subbasins (81%) that had the upland herbland community group below the median historical range, we would expect high risk of local extirpation for those species dependent on the abundance of the upland herbland community group. However, for the 11 patches of 30 subbasins in which the upland herbland community group existed within or above its historical range, we would expect a lower risk of local extirpation (table 3.169; map 3.56). Eight of the 11 patches were concentrated within the Central Idaho Mountains, Owyhee Uplands, Upper Snake, and Snake Headwaters ERUs. The most extensive patch (11 subbasins) occurred within the Central Idaho Mountains ERU. The Oregon and Washington portions of the Basin contained five small patches, each within a single subbasin that was isolated by expansive distances from the others.

Upland Shrubland

The Basin was dominated by subbasins (61%) in which the upland shrubland community group existed below its 75 percent median historical range (table 3.167, map 3.57). The 31 subbasins in which this community group occurred within its median historical range were distributed across 9 patches that ranged in size from 1 to 11 subbasins (table 3.168; median patch size = 2.0 subbasins). Most of these 31 subbasins were concentrated within the Northern Great Basin and Owyhee Uplands ERUs. Similarly, many of the 52 subbasins in which the upland shrubland community group existed within or above the median historical range were found in the Northern Great Basin and Owyhee Uplands ERUs. Some of these 52 subbasins were also concentrated in the Central Idaho Mountains ERUs. These 52 subbasins existed within 8 patches (table 3.169). The most extensive patch (39 subbasins) was continuous throughout the Northern Great Basin, Owyhee Uplands, and Central Idaho Mountains ERUs. In this extensive area, we would expect a low risk to persistence of species that are dependent on the availability of the upland shrubland community group. The seven remaining patches ranged in size

from one to six subbasins, and were widely distributed across the Northern Cascades, Columbia Plateau, Blue Mountains, Northern Glaciated Mountains, and Upper Clark Fork ERUs. In these seven remaining patches, and also in the subbasins (61%) that had less than 75 percent median historical range extent of the upland shrubland community group, we would expect a greater risk to persistence of the species dependent on upland shrubland availability.

Upland Woodland

Subbasins that had a substantial component of the upland woodland community group were nearly evenly distributed between those which contained this group below its 75 percent median historical range (41%), and those in which this community group occurred above that range (46%; table 3.167; map 3.58). The 14 subbasins (13%) in which the upland woodland community group occurred within its median historical range were widely distributed across the Basin in 9 patches that ranged in size from 1 to 4 subbasins (table 3.168; median patch size = 1.0 subbasin).

Within the subbasins (59%) that had the upland woodland community group within or above the median historical range, we would expect a relatively low risk to persistence of those species dependent upon the availability of the upland woodland community group (table 3.169). Four patches of 63 subbasins in which the upland woodland community group existed within or above its historical range were widely distributed across all but the northern Idaho and Montana portions of the Basin. The most extensive patch (58 subbasins) extended from the western portion of the Northern Glaciated Mountains ERU through the Northern Cascades, Columbia Plateau, Southern Cascades, Blue Mountains, Northern Great Basin, and Owyhee Uplands ERUs. The three remaining patches, which ranged in size from one to four subbasins, were located in the Central Idaho Mountains and Snake Headwaters ERUs.

Terrestrial Community Group Departure Discussion

Of the 12 terrestrial community groups for which we determined departure indices, the early- and late-seral lower montane forest communities departed the most from their historical ranges. Within forested settings, the extents of the montane and subalpine forest communities were more similar to the historical period conditions compared with the lower montane forest communities. The average subbasin frequency within Class 3 departures across early-, mid-, and late-seral structures was approximately 7, 15, and 17 percent for lower montane, montane, and subalpine communities, respectively. No more than 10 percent of the subbasins that comprised substantial components of lower montane forest communities contained those communities within their 75 percent median historical range. However, two community groups in each of the montane and subalpine forest settings approached nearly 20 percent frequency of subbasins falling within their respective median historical ranges (table 3.167).

Since the lower montane forest settings tended to have shorter fire-return intervals, occur on more accessible landforms (for example, level topography), and be closer to human settlements, they typically have been affected by past fire suppression and timber harvest activities to a much higher degree than either montane or subalpine forest settings. Conversely, subalpine forest settings probably more closely approximate their historical conditions because (1) successional change occurs at a slower rate in colder environments, (2) a higher relative proportion of area has been allocated to wilderness and wilderness-like management prescriptions, and (3) subalpine forests have typically been much less accessible to efficient fire suppression and timber harvest activities.

Our departure indices indicated that homogenization of forest structures occurred in the lower montane and montane forest settings. The frequency of subbasins in which early- and late-seral lower montane and montane forest community groups were below their median historical ranges was relatively high (51-94%), as was the

Map 3.58—Broad-scale habitat departure of the upland woodland terrestrial community group. The term "terrestrial community type" used in this map title is actually "terrestrial community group"; terrestrial community types were aggregated into groups for analysis of broadscale habitat departures.

frequency of subbasins in which mid-seral lower montane and montane forest community groups occurred above their historical ranges (approximately 58%). Thus, across most of the Basin in which lower montane and montane forest settings constituted a substantial component of the subbasins, early- and late-seral structures declined, whereas mid-seral structures increased.

The above-mentioned pattern of forest structure homogenization was not apparent within subalpine forest settings. The frequencies of subbasins were dominated by those in which early-seral structures exceeded their historical ranges, whereas mid- and late-seral structures occurred below their respective historical ranges. The observed decline of mid- and late-seral structures within subalpine forest settings was likely attributable to timber harvest activities and the relatively recent occurrence of large wildfires.

The significant declines we observed with the upland herbland community group within most (81%) of the subbasins across the Basin were primarily attributable to agricultural development, and to a lesser degree, the encroachment of upland shrublands, coniferous forests, woodlands, and exotics. However, there were 10 subbasins in which the upland herbland community group exceeded its historical range. Most (80%) of these subbasins were generally wild to semi-wild, minimally to moderately roaded, and had cold to moist forest settings. Nine of 10 of these subbasins were also in areas where we observed the early-seral subalpine forest community group to be above its historical range. Consequently, the observed increase in upland herbland community groups within these subbasins was likely attributable to timber harvest activities and some relatively recent, large-scale wildfires. These activities probably converted some areas into grass/forb communities, which were misclassified as an upland herbland group instead of an early-seral forest group.

Of the subbasins that had a substantial composition of the upland shrubland community group, 61 percent had areas of this community below its median historical range. Conversions to agriculture, and to a lesser degree, the upland herbland, upland woodland, exotic herbland, and lower montane forest community groups, were responsible for these declines. Conversely, 22 subbasins had areas of the upland shrubland community group that exceeded its median historical range. Most (57%) of the subbasins in which we observed substantial increases in upland shrublands were also classified as having moderate to high rangeland integrity (Quigley and others 1996). However, nearly 30 percent of the subbasins in which upland shrublands increased were classified as having low rangeland integrity.

Of the subbasins that had a substantial component of the upland woodland community group, 41 percent had areas of this community group below its median historical range. Most of the upland woodland community group within these subbasins (located predominantly in the Blue Mountains, Central Idaho Mountains, Upper Clark Fork, and Snake Headwaters ERUs) was converted into the upland herbland community group (Jones and Hann 1996c). Conversely, conifer and juniper expansion into shrubland habitats was predominantly responsible for the occurrence of the upland woodland community group above its median historical range within 46 percent of the subbasins. More specifically, the expansion of western juniper was primarily responsible for the substantial increase of the upland woodland community group within many of the subbasins in the Oregon and southwest Idaho portions of the Basin. Expansion of mixed-conifer and limber pine (*Pinus flexilis*) woodlands was largely responsible for all other subbasins in which the upland woodland community group exceeded its historical range.

We recognize that the individual fitness and the population persistence of few species are closely correlated to the areal extent of only one community group. Instead, many species rely upon the availability and spatial juxtaposition of several community groups. Consequently, a multi-community departure approach (that is, similarity index) of indexing vegetation change may be a more powerful tool for predicting the population response of those species having more general habitat requirements.

We are undoubtedly faced with a deficiency of information pertaining to the broad-scale habitat relationships and population responses to habitat change for most species residing in the Basin. Furthermore, there is little likelihood that the information void will ever be satisfactorily filled for the majority of flora and fauna any time soon. We believe that our coarse-filter approach for quantifying broad-scale habitat change and providing some spacial context for those changes, has created a useful data set for predicting the population responses of inadequately investigated species.

Ecological Reporting Unit Broad-Scale Landscape Mosaics

The broad-scale mosaic patterns of physiognomic groups were summarized for the 13 ERUs of the Basin. For a brief review of the specific methods used in the following discussion see the "Physiognomic group patterns" subsection in the "Overview of Methods" section of this chapter, or see table 3.8 for a description of the physiognomic groups.

Blue Mountains ERU

Mosaic patterns changed across 89 percent of the Blue Mountains ERU between the historical and current periods (table 3.170). We detected a net increase of fragmented landscapes within the ERU during this period, which seemed to have been the result of transitions within the forest/woodland physiognomic groups. The shrubland physiognomic groups changed the least. The dominant transition that occurred within the Blue Mountains ERU was the reduction of landscapes characterized by mixed mid-seral and late-seral single-layer forest/woodland physiognomic groups, which changed mostly into landscapes that had either a more uniform pattern and/or which had lost their late-seral single-layer forest/woodland physiognomic group. The next most dominant transitions occurred in rangeland habitats where landscapes characterized by a uniform herbland physiognomic group were converted into landscapes characterized by herbland and agriculture mixed physiognomic groups (that is, herbaceous landscapes were fragmented by agricultural types).

Central Idaho Mountains ERU

Mosaic patterns of physiognomic groups changed throughout most (82%) of the Central Idaho Mountains ERU between the historical and current periods (table 3.170). We detected a marginal net increase (6%) of uniform landscapes throughout the ERU. A single transition dominated the landscapes of this ERU—a decrease in areal extent of mixed mid-seral and early-seral forest/woodland physiognomic groups. The transitions within this group suggested that it became more uniform and older.

Columbia Plateau ERU

Mosaic patterns changed throughout 87 percent of the Columbia Plateau ERU (table 3.170). The ERU appeared to have been substantially fragmented—a trend of more fragmented patterns occurred across 47 percent of the ERU. The ERU was dominated by areal declines of the uniform herbland and uniform low shrub physiognomic groups, which were extensively converted to the agriculture physiognomic group across nearly 94 and 68 percent of their areas, respectively. Conversely, the extent of mixed herbland and agriculture physiognomic groups measurably increased between the historical and current periods.

Lower Clark Fork ERU

Mosaic patterns across virtually the entire Lower Clark Fork ERU changed between historical and current periods (table 3.170). Nearly 85 percent of the ERU had been transformed into more uniform pattern classes. In fact, the uniform pattern class did not occur in the historical period, yet composed nearly 54 percent of the ERU in the current period. Transitions were dominated by changes of two patterns. The most dominant landscape change detected was the decrease in the areal extent of mixed mid-seral and early-seral forest/woodland physiognomic groups, and the subsequent increase in the uniform mid-seral forest/woodland physiognomic group.

Northern Cascades ERU

Mosaic patterns throughout nearly the entire Northern Cascades ERU changed between the historical and current periods (table 3.170). The major trend in pattern was toward more homogeneous landscapes, which increased across 27 percent of the ERU. The increased landscape uniformity was mostly attributable to a reduction of mixed mid-seral and late-seral forest/woodland physiognomic groups, and the subsequent increase of the uniform mid-seral forest/woodland physiognomic group.

Northern Glaciated Mountains ERU

We detected changes of mosaic patterns throughout nearly all of the Northern Glaciated Mountains ERU (table 3.170). Landscapes across 59 percent of the ERU became more homogeneous between the historical and current periods. The most dominant transitions that occurred involved an increase in the uniform mid-seral forest/woodland physiognomic group, at the expense of both early- and late-seral forest/woodland physiognomic groups.

Northern Great Basin ERU

Mosaic patterns remained relatively stable throughout most (69%) of the Northern Great Basin ERU, although we detected a marginal net increase (2%) of more fragmented subwatersheds (table 3.170). Most of the fragmentation was attributable to a reduction of mosaic low shrub and mid shrub physiognomic groups, and the subsequent increase in areal extent of mosaic low shrub and herbland, and mixed low shrub and herbland physiognomic groups.

Owyhee Uplands ERU

Although we detected a net increase of 25 percent in the proportion of more fragmented landscapes in the Owyhee Uplands ERU, the mosaic patterns of most (58%) subwatersheds within the ERU did not change between the historical and current periods (table 3.170). Most of the fragmentation occurred in the uniform low shrub physiognomic group, which decreased by approximately 37 percent (the dominant transition within the ERU). The majority of this decrease was accounted for by increases in mosaic low shrub and herbland, mixed low shrub and herbland, and mixed herbland and agriculture physiognomic groups.

Snake Headwaters ERU

We detected changes of mosaic patterns across 92 percent of the Snake Headwaters ERU (table 3.170). A substantial (46%) trend toward more uniform patterns was evident across nearly 23 percent of the ERU. The increase in uniformity seemed to be attributable to an increase in area of the mid-seral forest/woodland physiognomic group, and subsequent declines of the late-seral forest/woodland and early-seral forest/woodland physiognomic groups. The dominant landscape transition that occurred within the Snake Headwaters ERU was an increase in the uniform mid-seral forest/woodland physiognomic group at the expense of the mixed mid-seral and late-seral multi-layer forest/woodland, and mosaic mid-seral and late-seral multi-layer physiognomic groups. Other less dominant changes included a decline of mixed mid shrub and mid-seral forest/woodland physiognomic groups, which changed mostly to mixed mid shrub and early-seral forest/woodland physiognomic groups.

Table 3.170—Summary of broad-scale mosaic pattern changes within Ecological Reporting Units (ERUs).

Upper Klamath	(--)	4	High
Upper Snake	(++)	22	Moderate

[1]Fragmentation trend assessment of coarse mosaic patterns, that is uniform, mosaic, and mixed: (+) = Slightly fragmented (≤ 5% trend); (++) = Moderately fragmented (6-30% trend); (+++) = Substantially fragmented (≥31% trend); (-) = Slightly more uniform (≤ 5% trend); (--) = Moderately more uniform (6-30% trend); (---) = Substantially more uniform (≥31% trend).

[2]Stability Index = proportion of mosaic patterns that remained stable between historical and current periods.

[3]Landscape departure indices were relativized among ERUs. Low departures had PD <33.3; Moderate departures had PD = 33.3 to 66.6; High departures had PD >66.6. See the "Methods" section of this chapter for derivation of PD (Departure Index).

Southern Cascades ERU

We detected broad-scale pattern changes across 86 percent of the Southern Cascades ERU (table 3.170). Fragmented patterns increased across approximately 6 percent of the ERU. The dominant landscape transitions involved a decrease in mixed mid-seral and late-seral single-layer forest/woodland physiognomic groups, which were replaced by mixed late-seral single-layer and late-seral multi-layer forest/woodland physiognomic groups. The increase of fragmented landscapes occurred primarily in the forest/woodland physiognomic groups. Secondarily, fragmentation increased in rangeland physiognomic groups due to agricultural development.

Upper Clark Fork ERU

Mosaic patterns varied between the historical and current periods on approximately 85 percent of the Upper Clark Fork ERU (table 3.170). We detected a substantial increase of more uniform landscapes across 44 percent of the ERU. The dominant landscape transitions that occurred were the result of the development of the early-seral forest/woodland physiognomic groups, and to a lesser degree, the areal decline of the late-seral forest/woodland physiognomic groups. For example, the uniform mid-seral forest/woodland physiognomic group increased at the expense of the mosaic mid-seral and early-seral physiognomic groups, and mixed mid-seral and late-seral multi-layer forest/woodland physiognomic groups.

Upper Klamath ERU

We detected a change of mosaic patterns across nearly all (96%) of the Upper Klamath ERU (table 3.170). Landscape patterns became more uniform across 22 percent of the area. The most dominant transitions suggested that landscapes composed by the forest/woodland physiognomic groups became older and more homogeneous. For example, the mixed mid-seral and late-seral forest/woodland physiognomic groups transformed into the mosaic or uniform late-seral forest/woodland physiognomic groups. These types of transitions occurred across 34 percent of the ERU.

Upper Snake ERU

Most (78%) of the mosaic patterns of subwatersheds within the Upper Snake ERU changed between the historical and current periods (table 3.170). A net increase of more fragmented landscapes occurred throughout 16 percent of the ERU. The transition matrices indicated that the increase of fragmented patterns occurred primarily within the uniform low shrub physiognomic group, which was converted to mixed and mosaic patterns that included the herbland physiognomic group. We also detected an increase in the uniform herbland physiognomic group, nearly all of which originated from the uniform low shrub physiognomic group.

Summary of Regional Broad-Scale Landscape Trends

Not surprisingly, three anthropogenic terrestrial community groups (that is, agricultural, urban, and exotic herbland) did not occur historically (table 3.171). Although the agricultural community group composed approximately 14 percent of the LCA during the current period, the exotic herbland and urban community groups did not compose substantial proportions of the area. As mentioned previously, we suspect that current period estimates of exotic vegetation prevalence in the Basin were too low. The barren/rock, alpine, and water community groups did not vary substantially between the historical and current periods.

In forested settings, an increasing fragmentation trend was observed between the historical and current periods for the lower montane community group and, to a lesser extent, the subalpine forest community group (table 3.171). However, the pattern indices of the montane forest community group indicated a trend toward increasing uniformity during this time interval. The lower montane forest community group exhibited significant declines in areal extent and mean patch size, while the number of patches increased. Although the areal extent of the subalpine forest community group did not decline substantially, the mean patch size index decreased significantly, while the patch number index increased significantly.

The most substantial changes in the areal extent of a community group across the LCA were the increase of the agricultural group, and the subsequent decrease of the upland herbland and upland shrubland community groups (table 3.171). In rangeland settings the upland shrubland and upland herbland community groups became much more fragmented, while the upland woodland group had a trend of increasing uniformity. We observed significant declines of areal extent, largest patch, and mean patch size indices for both the upland shrubland and upland herbland groups. Conversely, the number of patches of both groups increased significantly between the historical and current periods. On the other hand, the upland woodland community group had ecologically significant increasing trends for areal extent, largest patch, and mean patch size indices.

As a whole, the current period LCA appeared to be substantially more fragmented than the historical landscape (table 3.172). The largest patch and mean patch size indices decreased significantly, while the patch number index increased. As expected, patch richness increased due to the addition of three anthropogenic community groups (urban, agricultural, and exotic herbland) in the current period landscape. Although both diversity and evenness indices increased, and the contagion index decreased, the changes were not ecologically significant.

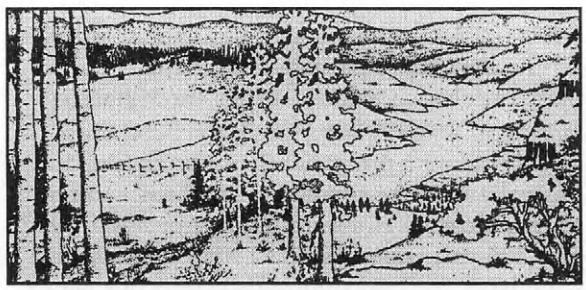
Broad-Scale vegetation patterns discussion

Our comparison of the historical and current period landscape patterns had inherent limitations as a consequence of differing methodologies and resolutions used in developing each broad-scale vegetation layer. We tried to lessen these inherent limitations by (1) resampling at a much broader resolution (that is, 4-km^2), (2) by comparing relatively coarse vegetation types (that is, terrestrial community groups), and (3) by considering only relatively large magnitudes of change (that is, $\geq$ 20%) as ecologically significant. However, at best our findings, which resulted from the comparison of values derived from different methods and different time periods, should be regarded as working hypotheses. In addition, many, if not most of landscape pattern changes occur at a much finer scale than we used in our analysis. Consequently, our analysis captured broad-scale changes but likely overlooked the more subtle changes that had occurred.

Taken in its entirety, the landscapes of the Interior Columbia Basin and portions of the Klamath and Great Basins became substantially more fragmented between the historical and current periods. However, the coarse-grained fragmentation that occurred within the area as a whole was not consistently apparent among the broad-scale vegetation types (that is, among the broad-scale terrestrial community groups or physiognomic groups) that we assessed, or among the ERUs. For example, landscape patterns throughout roughly one-half of the ERUs became more fragmented, while patterns became more homogenous throughout other ERUs. In addition, we detected increasing fragmentation trends within four terrestrial community groups (lower montane forest, subalpine forest, upland herbland, and upland shrubland), but a trend of increasing homogeneity within two community groups (montane forest and upland woodland). The two opposing trends were not at all independent. The montane forest community group seems to have expanded throughout the LCA, at the expense of the lower

montane forest, and to a lesser extent, the subalpine forest community. Similarly, in the rangeland settings, the upland woodland community group expanded into the upland shrubland community, and to a lesser extent, into the upland herbland community. However, the substantial fragmentation of the upland herbland and upland shrubland community groups was predominantly a consequence of the agricultural conversion of 14 percent of the LCA.

Four primary agents of change were largely responsible for the coarse landscape pattern changes we detected. In forest environments, the primary agents of change included successional processes, fire suppression, and timber harvest activities. As a consequence, a large proportion of the lower montane forest community group converted to the montane forest community group. Fire suppression and successional processes had permitted many of the shade-tolerant and fire-intolerant species (for example, Douglas-fir and grand fir), more commonly associated with the montane forest community, to invade and prosper on sites that would be expected to support the lower montane forest community group (dominated by ponderosa pine). Timber extraction activities commonly exacerbated this situation by targeting the removal of ponderosa pine and promoting stand development of Douglas-fir and grand fir. Fire suppression, in rangeland environments, also contributed to the expansion of the upland woodland community group into the upland shrubland community group. However, as stated previously, agricultural development within the upland herbland and upland shrubland community groups was the dominant agent of change within rangeland environments.



Our analysis suggests that a species whose fitness is positively correlated to an increasing area and larger, more contiguous patches of the agricultural, exotic herbland, montane forest, and upland woodland community groups would likely have a higher probability of long-term persistence during the current period, than they had historically. On the other hand, species whose fitness is negatively correlated to the extensive fragmentation of the lower montane forest, upland herbland, and upland shrubland community groups were likely most at risk.

RANGELAND ECOLOGY AND GRAZING MANAGEMENT

Causal Agents in Landscape Conditions and Trends On Rangelands and Riparian Areas

This section summarizes the detailed reports written by the project staff on causal agents in landscape trends on rangelands and riparian areas. Causal agents, including herbivory by large herbivores, livestock grazing in riparian areas, western juniper expansion, exotic plants-noxious weeds, and cheatgrass, are each discussed within this section. We propose that much of the literature and findings presented in this section could be applied in rangeland and riparian ecosystems throughout the western United States and therefore should be of use to rangeland managers both within and outside the Basin.

We continue in this section, as in previous sections, to refer to species using their common names and to provide scientific names for each species when first cited in the text. Common and scientific names of all plant species discussed in this section are provided in appendix 3-I.

Herbivory by Large Herbivores

The following subsection originates primarily from Grayson (1993), which is a text that focuses on the Pleistocene and Holocene natural history of the Great Basin, and a report written by ICBEMP staff (Leonard and Karl 1995a).

Large herbivores and herbivory in the Pleistocene and Holocene—Vegetation throughout the Basin was in a continued state of flux during the late Pleistocene (roughly 132,000 to 10,000 years ago; Grayson 1993) and the Holocene (the last 10,000 years; Grayson 1993, Miller and others 1994). Changes in climate and frequency of fire were probably the primary disturbances influencing vegetation change before Euro-American settlement. Herbivory by native grazers played a less dominant role in the late Pleistocene and Holocene (Aikens 1986, in Miller and others 1994; Grayson 1993; Martin 1967, in Miller and others 1994; Miller and others 1994).

Large herbivores present during the late Pleistocene in the Basin included horses (*Equus* spp.), flat-headed peccaries (*Platygonus compressus*), camels (*Camelops hesternus*), mammoths (*Mammuthus columbi* and *M. primigenius*), Harlan's ground sloth (*Glossotherium harlani*), large-headed llama (*Hemiauchenia macrocephala*), and possibly Harlan's muskox (*Bootherium bombifrons*) (Allison 1966, in Grayson 1993; Howe and Martin 1967, in Grayson 1993; Grayson 1993). Of these, horses, camels, and mammoths were the most common on the landscape. Mammoths probably were gregarious and were grazers. Open grasslands have produced the most abundant quantities of mammoth remains. Flat-headed peccaries were believed to be gregarious, and probably preferred open environments. Harlan's muskox apparently preferred open environments as well. These large herbivores, and various other mammals, became extinct in the late Pleistocene. The above-mentioned herbivores were undoubtedly encountered by the earliest human occupants of the Great Basin (Grayson 1993).

Large herbivore abundance and diversity, at least in the Great Basin portion of the Basin, were apparently much reduced during the Holocene compared with the late Pleistocene (Grayson 1993). Elk were present in the Great Basin portion of the Basin at the end of the late Pleistocene and during the early Holocene (approximately 11,000 to 7,200 years ago; Grayson 1993). However, elk abundance declined substantially after this period. Studies have indicated that large herbivore abundance and diversity declined in the Great Basin portion of the Basin from the early Holocene (about 10,000 to 7,500 years ago) to the mid (about 7,500 to 4,500 years ago) and late Holocene (last 4,500 years). Grayson (1993) maintained that the Great Basin, like so many other parts of North America, supported a far richer large mammal fauna toward the end of the Pleistocene than it does today. Apparently, chief among those mammals were horses, camels, and mammoths.

In the late Holocene, prior to Euro-American settlement, environmental conditions and hunting pressure by Native Americans appeared to keep large herbivore populations low. Grazing impacts by large herbivores were probably light, except in localized areas. Grazing by large and small mammals, birds, and insects was likely characterized by heavy and light cyclic extremes that were somewhat attributable to cyclic extremes in herbivore populations (Miller and others 1994). Grazing was likely seasonal, with animals migrating between upper-elevation summer range and lower-elevation winter range (Burkhardt 1996, Miller and others 1994). Consequently, the effects of selective grazing by native herbivores was probably minimal and did not substantially affect interspecific competition and vegetation composition, even during periods of high population densities (Miller and others 1994).

Since the historical period, plant composition of rangelands (the dry grassland, dry shrubland, cool shrubland, woodland, and riparian PVGs) within the Basin changed at unprecedented rates, due to disturbances associated with Euro-American settlement. Agricultural development, introduced livestock (horses, cattle, sheep) and exotic plant species, elevated CO_2 levels, altered fire regimes and hydrologic cycles, recreation, and mining, interacted with a gradual change in climate to substantially change the landscape composition and structure of rangelands within the Basin (Miller and others 1994).

Grazing pressure increased substantially during the Holocene as Euro-American introduced their horses, sheep, and cattle. In the early-1900s, Griffiths (1902, 1903) reported declines in native vegetation abundance and condition in the Great Basin portion of the Basin and in eastern Oregon and Washington. He attributed this decline to the introduction of domestic livestock (particularly cattle and sheep) and wild horses to the region, and excessive livestock grazing pressure. Grass (for example, bluebunch wheatgrass) abundance was declining over most of the rangeland on his reconnaissance route, and he was beginning to observe excessive browsing of shrubs, particularly shrubs of the salt desert shrub PVT such as winterfat. The excessive livestock grazing pressure and its deleterious effects to native vegetation were particularly apparent to Griffiths on Steens Mountain in southeast Oregon. Grassy areas (characterized by prevalence of sheep fescue, and thus what we would refer to as the fescue-grassland PVT), riparian areas (characterized by willow), and areas with aspen, were particularly overused by livestock. Griffiths estimated that in 1901, 182,500 sheep, or 175 sheep per square kilometer, were present on Steens Mountain. In addition, ranchers on the few cattle ranches that were in the lowlands surrounding Steens Mountain placed their cattle on the mountain in the summer.

Grazing pressure exerted on native vegetation of the Basin by large herbivores has thus fluctuated over time. Large herbivores were more abundant and diverse during the Pleistocene compared with the Holocene, and grazing pressure probably declined in the Holocene. Grazing pressure increased substantially as Euro-Americans settled the Basin and introduced sheep, cattle, and horses, perhaps even greater than during the Pleistocene. Deleterious effects on the native vegetation,

particularly during the late-1800s and early-1900s, were clearly evident. We concur with Grayson (1993) that "The native grasses of the floristic Great Basin are not adapted to *heavy* [italics added] grazing by large mammals."

Livestock grazing and vegetation dynamics (historical to current period)—Platou and Tueller (1985) proposed that livestock grazing, and livestock grazing systems, that emulate native grazing regimes of the vegetation communities in the late Holocene (pre-Euro-American settlement) would be more compatible with the evolutionary history of vegetation in the Great Basin. However, pre-Euro-American settlement conditions no longer exist in the Basin. Agricultural and urban development, livestock herbivory (as described by Miller and others 1994), the introduction of exotic plants, and changes in disturbance regimes have resulted in unprecedented changes. Given that landscape conditions have changed in the Basin, we addressed two pertinent questions in our analysis.

1) Can ecosystem functions that have been altered by improper livestock management since the historical period be restored by removing livestock?

Laycock (1994) provided a review of literature comparing the implications of livestock grazing versus no grazing on current period rangelands, and concepts of "state-and-transition" models versus traditional "climax" models to explain vegetation succession and retrogression. Vegetation change on the more mesic rangeland potential vegetation types seems to correspond most closely with the traditional climax model. In this model, the removal of grazing pressure results in improvement through secondary succession (fig. 3.15). The PVTs in the Basin that best fit this model include the riparian types (for example, cottonwood riverine and mountain riparian low shrub), aspen, the grassland types (for example, wheatgrass grassland and fescue-grassland), and open ponderosa pine-grassland types (for example, fescue-grassland with conifer and interior ponderosa pine). We propose that there are exceptions within these types where successional advancement might not be realized, especially in cases of excessive livestock grazing pressure and/or exotic plant invasion.

In contrast, most current period arid and semi-arid rangeland PVTs remain stable at one or more lower (less advanced) successional states for long periods of time after removal of livestock, unless humans intervene in the form of rangeland modifications (for example, seedings). Nearly all sagebrush grassland PVTs (with or without juniper) and the salt desert shrub PVT are included in this category and best fit the state-and-transition model. This model defines vegetation states as:

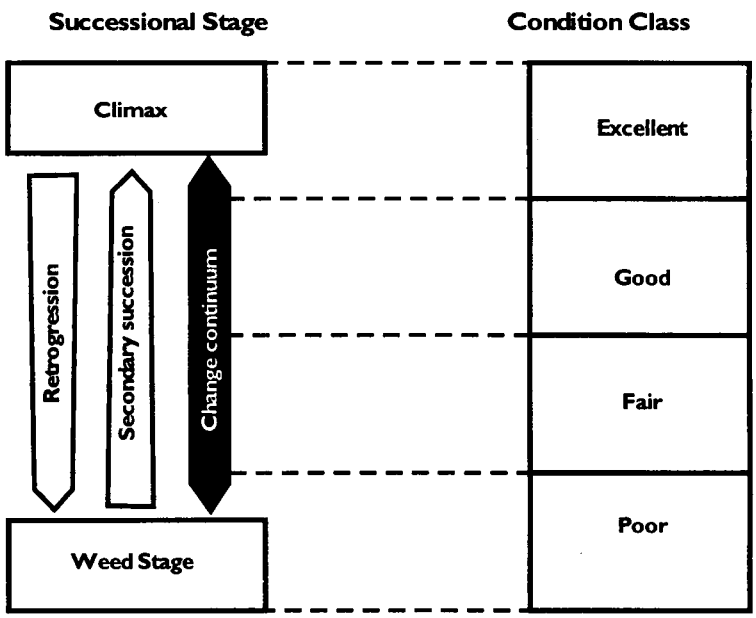

Figure 3.15—Climax model for vegetation succession—The climax model of vegetation succession and the approximate relationships between rangeland condition and degree of retrogression from climax conditions (adapted from Vavra and others 1994).

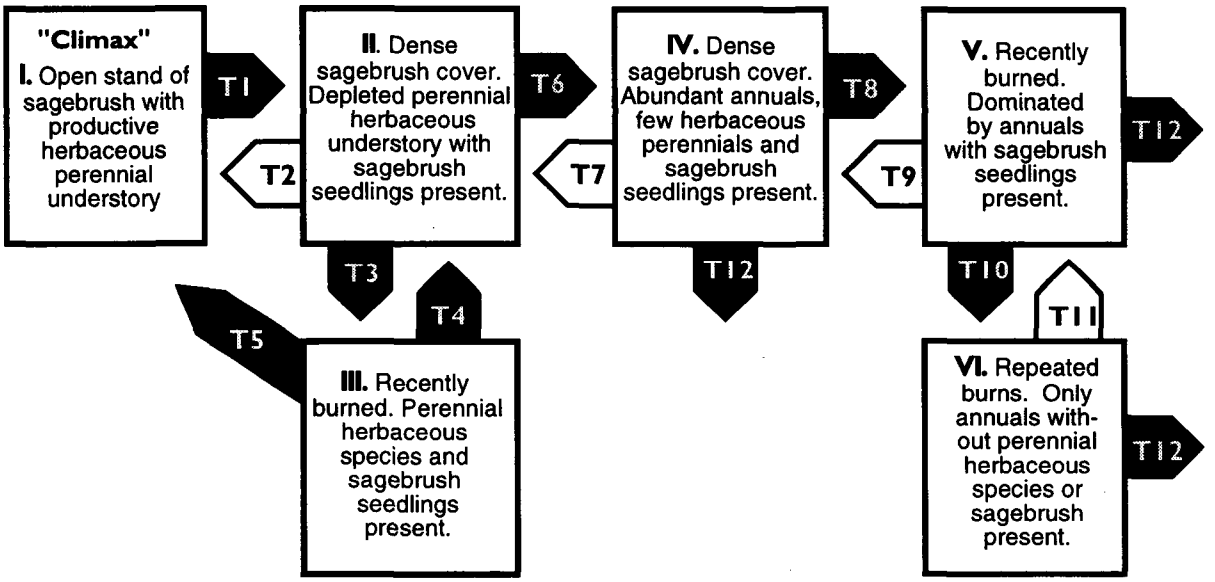

Figure 3.16—State-and-Transition Model for sagebrush grass ecosystem. States I, II, and III exist in areas without exotic annual species (for example, cheatgrass or medusahead). State I is the "climax" or condition undisturbed by livestock grazing. Transition arrow T1 represents excessive livestock grazing pressure which causes deterioration of the understory and increased density and vigor of sagebrush. State II is dominated by sagebrush and will remain stable for long periods of time. Transition T3 is fire or some other force (for example, insects, disease, or a herbivore that consumes sagebrush) that reduces the sagebrush, which permits the understory to improve (State III). With proper livestock grazing management (Transition T5), State III can transition back to a state resembling State I. With excessive livestock grazing pressure (Transition T4), State III will transition to State II, and sagebrush will again dominate the stand. State IV represents areas subjected to excessive livestock grazing pressure where a well-adapted, annual like cheatgrass exists. Continuous excessive livestock grazing pressure (Transition T6) in State II results in State IV, where perennials in the understory have been replaced by annuals. The transitions of State IV to State V (T8), and State V to State VI (T10), represent the role of fires in the conversion to a stable cheatgrass-dominated plant community. Transition T12 represents intervention by humans, for example the seeding of exotic perennial grasses, such as crested wheatgrass. The BLM, for example, plants strips of vegetative fuel breaks (greenstrips) consisting of crested wheatgrass, other grasses, forbs, and shrubs to slow the spread of fires (adapted from Vavra and others 1994).

recognizable, relatively stable assemblages of species occupying a site. Forces such as grazing disturbance or altered fire regimes can cause vegetation to cross a threshold, or transition (fig. 3.16). Once a threshold is crossed, removal of the disturbance will not necessarily result in a transition to a higher successional state without substantial inputs of energy or nutrients. Some functional improvement (for example, improved nutrient status and reduced erosion associated with microbiotic crust redevelopment) within a state might be accomplished with livestock removal in many situations, but we speculate that this improvement is probably not detectible with mid- or broad-scale assessments.

An example of an apparently stable vegetation state is the cheatgrass and/or medusahead dominated areas within some sagebrush grassland PVTs [particularly Wyoming big sagebrush (*Artemisia tridentata wyomingensis*)-warm]. Frequent fires result from the establishment of these highly flammable exotic annual grasses. Current period fire-return frequencies as low as five years largely prevent perennial grass or shrub establishment. Removal of livestock will not reduce fire frequencies and can exacerbate fire susceptibility through the subsequent accumulation of flammable litter.

2) Can livestock be managed in a manner that would be compatible with native plant communities in the Basin?

Archer and Smeins (1991) proposed that some traditional livestock grazing management practices were not compatible with native plant communities. The authors identified several examples of poor compatibility: (1) Traditionally, livestock are concentrated at artificially high levels. In contrast, densities of native herbivores varied seasonally and annually; (2) Fences prevent livestock from moving to new areas when the abundance of desired forages decreases. Consequently, traditional grazing practices result in higher frequencies and intensities of defoliation than would have occurred with pre-Euro-American settlement grazing regimes; (3) Mortality of native herbivores was a feedback loop that reduced grazing pressure, permitting recovery of native vegetation after periods of forage overuse. Supplemental feeding precludes mortality of livestock and thus maintains grazing pressure over a greater portion of the year and over a higher frequency of years, compared with grazing pressure that was exerted by native herbivores; and (4) Prolonged grazing in grasslands or savannas that existed in areas climatically and edaphically capable of supporting trees or shrubs has decreased the capacity of grasses to competitively exclude woody plants. It also concurrently reduced fire frequency, and usually, fire intensity, by preventing the accumulation of fine fuels.

Grazing systems have been promoted to mitigate or prevent the detrimental effects to native plant communities. Rest-rotation grazing has been suggested as a grazing system that approximates the manner in which native ungulates grazed the Great Basin shrub-grassland (Platou and Tueller 1985). Seasonal grazing (Vallentine 1990), characterized by livestock moving higher in elevation with increase of temperature and changes in plant phenology, might also approximate past grazing by native ungulates if constraints of land ownership, tenure, or administration do not prove to be problematic.

Under specific circumstances, rest-rotation, deferred, deferred rotational, and seasonal grazing systems have all been demonstrated to sustain rangeland vascular plant communities within the sagebrush grassland and pine-bunchgrass zones in the Basin (Vallentine 1990). However, none of these grazing systems have been conclusively more effective than light to moderate stocking levels under continuous seasonal use (Hart and Norton 1988, Heady 1975, Stoddart and others 1975, Vallentine 1990). Thus, despite the array of grazing systems conceived and promoted during the last 40 years in the United States, there has been considerable debate over their compatibility with native plant communities.

Grazing systems, and no grazing, are unlikely to elevate many plant communities in a low successional steady state to a higher successional state (Archer and Smeins 1991). Sustainable grazing management then, relies on knowledge of critical thresholds and manipulation of livestock so these critical thresholds are not exceeded. Continued stocking at near-normal levels during periods of moderate to severe drought is probably the greatest cause of range deterioration (Vallentine 1990). Reduced grazing intensities during drought, and for some time after drought, are necessary to minimize damage and hasten recovery of perennial vegetation. Frequency of drought in the Basin and frequency of years that are proposed as favorable for vegetation recruitment have been discussed in various portions of the "Results and Discussion" and are discussed in detail in the "Susceptibility of Rangeland Health to Management-Induced Disturbance Stresses" subsection.

Livestock Grazing in Riparian Areas

This subsection is a summarization of Leonard and Karl (1995b), which is an ICBEMP report based primarily on Kindschy (1994).

Riparian areas (U.S. Department of Interior 1992) are

> a form of wetland transition between permanently saturated wetlands and upland areas. These areas exhibit vegetation or physical

characteristics reflective of permanent surface or subsurface water influence. Lands along, adjacent to, or contiguous with perennially and intermittently flowing rivers and streams, glacial potholes, and the shores of lakes and reservoirs with stable water levels are typical riparian areas. Excluded are such sites as ephemeral streams or washes that do not exhibit the presence of vegetation dependent upon free water in the soil.

Riparian-wetland areas are grouped into two major categories: (1) lentic, which is standing water habitat such as lakes, ponds, seeps, bogs, and meadows, and (2) lotic, which is running water habitat such as rivers, streams, and springs. A preponderance of literature on livestock grazing in riparian areas is associated with lotic systems because of their much greater areal extent in the arid west, and the potentially greater negative affects associated with increased energies of running water.

Historical to current context—Historical evidence indicates that most riparian areas in the Basin have changed dramatically in the last 100 years. A major causal factor has been improper livestock grazing, defined by Chaney and others (1990) as, concentrations of livestock at the wrong time (that is, season), in too great a number (that is, intensity), for too long (that is, duration), or any combination of these factors that results in riparian area degradation. Other major factors have been changes in hydrologic regimes caused by dams, diversions, and irrigation, and to a lesser extent, disturbances associated with logging, roads, and recreational facilities.

Effects attributable to improper livestock grazing—Livestock grazing has occurred across most of the Basin (map 3.25). Riparian sites constitute only a small percentage (2-3%) of the Basin (table 3.18), yet livestock (especially cattle) activity has been disproportionately concentrated within riparian areas (Kovalchik and Elmore 1992, Marlow and Pogacnik 1986) compared with upland areas. Concentrated livestock activity has resulted in excessive herbage removal and physical damage by trampling. Some ramifications of excessive herbage removal and physical damage have included (1) reduced dissipation of stream energy, (2) an increased extent of bare soil and accelerated erosion, and (3) stream channel degradation, which has resulted in reduced floodplain recharge, lowered water tables, and reduced areal extent of riparian plant communities. Erosion and stream channel degradation have affected water quality by increasing suspended sediments. Water temperatures have increased due to the decline in shade provided by vegetation. Simplification of vegetation structural diversity and the presence of early-successional stages has resulted in less diverse and often less productive floral and faunal assemblages. Direct influences of livestock concentrations in riparian areas on water quality include bacterial and protozoal parasite contamination, and nutrient enrichment from fecal material in and near surface waters (Larsen 1996).

Proper functioning condition of riparian-wetland areas—Riparian-wetland capability and potential is defined by the interaction of three components: (1) vegetation, (2) landform and soils, and 3) hydrology. When the interaction of these three components is functioning properly, the negative physical ramifications described above are not apparent and the capability to produce desired biological attributes is maintained. Riparian-wetland areas are functioning properly when adequate vegetation, or large woody debris are present and able to (1) dissipate stream energy associated with high water flows, thereby reducing erosion and improving water quality, (2) filter sediment, capture bedload, and aid floodplain development, (3) improve flood water retention and groundwater recharge, (4) develop root masses that stabilize streambanks, (5) develop diverse ponding and channel characteristics to provide habitat, water depth, duration of water presence, and temperature necessary for fish production, waterfowl breeding, and other uses, and (6) support greater biodiversity (Barrett and others 1993).

Proper functioning condition can exist anywhere along the seral continuum, from early-seral to potential natural community, depending on the particular characteristics of the riparian-wetland area. Although proper functioning condition is viewed by the BLM as the minimum acceptable condition for any goal, management objectives might require vegetation composition, cover, or structure that are representative of advanced seral stages, beyond proper functioning condition. Riparian-wetland areas can be classified as proper functioning condition before they have achieved an advanced ecological status, but achievement of advanced ecological status, [defined in Barrett and others (1993) as "a community with a high coefficient of similarity to a defined or perceived potential natural community for an ecological site, usually late seral or potential natural community ecological status"], is the ultimate goal on Federal rangeland riparian-wetland areas (Barrett and others 1993, U.S. Department of Interior 1990). Advanced ecological status is the ultimate goal because successional advancement and/or increased cover, density, or structure of riparian vegetation is necessary for improvement of degraded systems. Livestock grazing can be implicated in the impedance of desired vegetation changes in many instances. Improvement of riparian areas also hinges on concomitant improvement of degraded uplands or maintenance of healthy upland vegetation. Proper livestock use can improve upland vegetation and result in increased infiltration rates, reduced overland flows, and increased water storage by stream systems (Elmore 1992).

An inventory and assessment of approximately 15,300 stream and shoreline kilometers of riparian areas in Oregon, Washington, Idaho, and Montana by the BLM shows that 31 percent are in proper functioning condition, 53 percent are functional at risk, and 16 percent are nonfunctional (U.S. Department of Interior 1994). Riparian-wetland areas are considered functional-at risk when they function, but are susceptible to degradation attributable to soil, water, or vegetation characteristics. Functional-at risk also indicates riparian areas that can respond rapidly to improved management.

Nonfunctional areas are believed to require stream channel evolution or mitigation of major alterations prior to achievement of proper functioning status. We speculate that the above-stated, percent categorization of functionality can be extrapolated to, and is indicative of, riparian systems within the Basin as a whole.

Livestock grazing strategies, grazing systems, and their effects—Although total exclusion of livestock is shown to improve conditions (Claire and Storch 1977, Duff 1977, Gunderson 1968, Winegar 1977), total exclusion is not always necessary to reduce negative impacts (Krueger and Anderson 1985). Land managers can accomplish riparian area improvement concomitantly with livestock grazing (Chaney and others 1990, Elmore 1992, Elmore and Kauffman 1994) through an increased emphasis on compliance to suitable grazing strategies and practices. There are limitations, however, associated with livestock grazing, because "In essence, livestock are NOT a 'tool' to improve riparian ecosystems. Rather, they are a cost that may often be accommodated and still enable successional advancement of riparian vegetation and attendant functional values [Kruger (sic) and Anderson 1985, Kindschy 1987]" (Kindschy 1994).

There are numerous prescribed grazing strategies for livestock that can be successful in riparian areas (Chaney and others 1990). Many options can be considered for inclusion in successful prescribed grazing strategies. These options can permit successional advancement of vegetation, while satisfying management requirements of the livestock enterprise. Pertinent options include:

1) Livestock type: The adverse effects on riparian vegetation from sheep can be substantially less than from other livestock types, particularly when sheep are herded. Herding keeps the animals out of riparian areas, except for short watering periods.

2) Livestock class: There are behavioral differences between young and mature animals (Swanson 1985). Yearling cattle are less apt to linger within riparian areas compared with cows, especially cows with calves, or bulls.

3) Season of use: The most harmful impacts to riparian vegetation from herbivory are incurred during summer months. Livestock tend to linger near water during the summer season. Willows, and likely other woody plant species, are susceptible to excessive herbivory during this season because the impact coincides with their maximum growth period. Conversely, livestock grazing during spring, autumn, and winter appears to be relatively less deleterious to riparian vegetation.

   a) Spring grazing—Compared with grazing during other seasons, spring grazing is possibly the least deleterious to the majority of riparian plant species (Platts and Nelson 1985, Shaw 1991), partly because of regrowth potential, and partly because livestock tend to avoid riparian areas in the spring. Removal of livestock before the hot summer months permits regrowth and physiological maintenance of plants. This regrowth functions as a filter for instream and flood flows, reduces water velocity, and promotes sediment deposition. Livestock tend to avoid riparian areas that are characterized by wet soil, cold temperatures, and immature forage in the spring (Kovalchik and Elmore 1992, Platts and Nelson 1985).

      Cattle concentrate their foraging effort in uplands rather than riparian areas in spring because forage palatability and climate are more favorable in uplands compared with riparian areas (Platts and Nelson 1985). Soil water availability often limits plant growth earlier in the growing season on upland areas compared with riparian areas; thus, regrowth of upland vegetation and replenishment of their root reserves is curtailed compared with riparian vegetation. Periodic year-long rest from grazing should be incorporated for upland vegetation in this instance.

   b) Summer grazing—Summer grazing, as previously mentioned, can be deleterious to woody species in riparian areas. Woody riparian species, such as willow, experience rapid tissue elongation during summer months. Removal of current year tissue growth for willow results in reduced regrowth potential (Kindschy 1989) in comparison with unbrowsed willow or willow browsed during the dormant periods of the year. Herbaceous species, such as sedges and rushes, can tolerate summer grazing, if periodic rest or deferment is provided for vigor and reproduction recovery. The attraction of livestock to streamside areas during summer often means that 90 to 95 percent of the adjacent upland areas receive little or no grazing pressure (Krueger and Bonham 1986).

   c) Autumn grazing—Autumn grazing has mixed effects on soil and vegetation. Removal of herbaceous material in autumn is not necessarily detrimental because physiologically, herbaceous species in upland and riparian areas have completed (or nearly completed) their current-year growth and have replenished their root reserves by this time. If the autumn herbaceous component is coarse and mature (Roath and Krueger 1982) or heavily used and unavailable for further consumption (Kauffman and others 1983, Kovalchik and Elmore 1992), use of woody species by livestock could increase. Recruitment of willow and black cottonwood can be jeopardized by autumn grazing (Kauffman and others 1983). Sedgwick and Knopf (1991) also noted that willows responded negatively to autumn grazing.

      Depending on the severity of herbage removal and trampling incurred during autumn grazing, stream banks can remain in a disturbed condition through the winter season. Without autumn vegetative

regrowth, riparian areas would be comparatively devoid of vegetative cover during late winter and early spring snowmelt, thus reducing bank protection and energy dissipation during high volume flows.

d) Winter grazing—Winter grazing or dormant-season grazing generally promotes riparian area recovery and maintenance (table 3.173). Herbaceous species have completed current-year growth and have replenished root reserves. To some extent, consumption of woody species does occur (Elmore 1992), and if the herbaceous component is snow covered, livestock can consume undesirable levels of woody tissue. However, Kindschy (1989) reported that willow, which was cut during the time of dormancy to simulate use by beaver, maintained vigor and growth characteristics similar to trees with no history of beaver use. This suggests that dormant-season herbivory might be less deleterious compared with growing-season herbivory, or that other factors related to livestock grazing require further investigation and evaluation. Additional research would aid in clarifying our understanding of herbivory on dormant woody riparian vegetation.

Winter grazing can be more prevalent on upland areas compared with riparian areas, especially in areas where cold air drains into the riparian zone. In these instances, riparian vegetation might benefit because of the shift of grazing to upland areas (Elmore 1992). Livestock trampling effects on soils attributable to winter grazing are less detrimental when soils are frozen (Sedgwick and Knopf 1987).

4) Duration of use: Short-duration grazing, characterized by high-intensity, low-frequency use (long rest period relative to the use period) can permit limited successional advancement of the herbaceous component, but is less beneficial to the woody component. Growth of the woody component during the rest period can be nullified by consumption by livestock during the high-intensity use period.

5) Livestock numbers: A reduction in livestock numbers does not translate into a proportional reduction in grazing pressure in riparian areas. Consequently, a reduction in livestock numbers within pastures where riparian plant communities are of concern will typically have little positive effect on the riparian system (Harlow and others 1989, Marlow 1988). Riparian areas will typically continue to experience a greater proportion of the grazing pressure compared with the uplands. Reduction of livestock numbers in a magnitude sufficient to reduce grazing pressure in riparian areas does not address the more likely causal problems of the riparian area degradation, which include inappropriate livestock distribution, season of use, or duration of use.

6) Livestock exclusion: The exclusion of livestock permits initiation of recovery mechanisms in degraded riparian systems (see "No Grazing" in table 3.173). Livestock exclusion can result in a rapid rate of improvement of highly-sensitive riparian areas, such as critical spawning areas for sensitive fish species. Livestock exclusion from riparian areas apparently does not always, however, result in enhancement of spawning for salmon, compared with riparian areas where livestock are present (Johnson and others 1995). Livestock exclusion will result in immediate improvement of nonfunctional riparian systems only if channel development is at a stage where improvement is possible. Downcut systems that have only recently attained a new base level will not immediately benefit from any option, until the channel system has widened enough to permit vegetation establishment that is sufficient to resist higher flows (Barrett and others 1993).

7) Livestock selection: Swanson (1985) and Roath (1979) indicated that within breeds, or even herds, certain individuals tend to loiter in riparian areas more than others. Culling has been suggested to rid herds of individuals that spend disproportionate amounts of time in riparian areas (George 1996). Additional research is needed in this topic area.

(8) Attraction of livestock out of riparian areas: George (1996) provides a review of practices that tend to reduce the time livestock spend in riparian areas. Seeding of upland areas (Durbin 1977, Storch 1978), seeding and fertilization of the upland areas, and recently burned areas (Swanson 1985) all can result in reduced grazing pressure in riparian areas. Supplemental feeding of livestock, away from water, can also improve livestock distribution (McDougald and others 1989) in winter pastures. Water developments apparently have had mixed results. Stockwater development can significantly reduce use of stream and spring areas (Clawson 1993), although Gillen and others (1985) reported that cattle preferred the quality of free-flowing water. Miner and others (1992) observed that watering tanks resulted in less livestock use near streams, presumably because of warmer water temperatures in the tank compared with free flowing sources of water.

9) Herding: Herding (that is, controlling animal movement typically using horses or vehicles) has been used successfully to direct livestock activity away from riparian areas (Chaney and others 1990, Claire and Storch 1977, Storch 1978). Herding in the Trout Creek Mountains area of southeastern Oregon in the Northern Great Basin ERU has resulted in mitigation of livestock impacts in riparian systems that contain the Lahontan cutthroat trout (*Oncorhynchus clarki henshawi*), a federally listed threatened species.

10) Barriers: Various types of barriers can be used to discourage livestock activity in particularly sensitive areas (George 1996). Prototype electronic (fenceless) control has been tested with positive results (Quigley and others 1990) in discouraging or excluding livestock; however, further research is needed on equipment development and testing.

As previously mentioned, these options can be integrated into prescribed grazing strategies for riparian areas. Our discussion will now focus on several grazing systems and their effects in riparian areas. Grazing systems are defined in Society for Range Management (1989) as specialized grazing management that defines the periods of grazing and non-grazing.

1) Three-pasture, rest rotation—The typical grazing timing for a pasture in this system is for grazing in spring of year 1, summer of year 2, and rest in year 3. Shrub consumption is light in year 1 because upland herbaceous material is green and palatable in the spring. Grazing in year 2 is timed to begin after upland grasses have produced ripe seed (usually in mid July). The desired usage for upland grasses in year 2 is 60 percent or less, but because the upland vegetation has dried and has lost palatability, concurrent usage of riparian herbaceous vegetation might be 80 to 90 percent, or more. Shrub usage escalates concurrently with riparian herbaceous usage levels exceeding 45 percent. The benefit of this system is that it promotes plant vigor, seed production, seedling establishment, root production, and litter accumulation of the herbaceous component (compared with season-long grazing). A limitation of this system is that shrub usage in the second year of the cycle can exceed the growth accruing from year 1 and year 3 of the cycle.

   In summary, this grazing system was designed to satisfy the physiological needs of herbaceous species and does not satisfy the needs of woody species to the same extent (see table 3.173). Woody species in riparian

areas generally decline with this grazing system (Elmore and Kauffman 1994). Excessive shrub utilization however, can be prevented by restricting utilization of riparian herbaceous vegetation to 50 percent or less in the second year (seed-ripe year) of the cycle (Clary and Webster 1989). Additional favorable practices include managing the riparian area as a separate pasture (managed according to the physiological needs of the riparian plant species), or adding more pastures to achieve additional rest from grazing pressure (Elmore 1992).

2) Three-pasture, deferred rotation—As described in Elmore (1992), deferment of grazing in this system is rotated among pastures and years. A pasture on a 3-year cycle would be grazed in early spring in year 1, late spring in year 2, and summer in year 3. Other deferred rotation systems have been described, for example the four-pasture system in Heitschmidt and Taylor (1991). The three-pasture, deferred rotation system does not promote growth of woody species, because of summer usage. The herbaceous component benefits from the periodic growing season rest. Thus, with respect to the response of the herbaceous and woody components, this system is similar to the three-pasture/rest rotation system (table 3.173).

3) Early rotation—As described in Elmore (1992), a pasture in the early rotation system is rested for a portion of the growing season. A pasture might be grazed in early spring in year 1, and late spring in year 2. Effects on the herbaceous and woody vegetation are generally positive (table 3.173). Benefits to herbaceous vegetation accrue from the regrowth after livestock are removed. However, seed and root production are not always enhanced. Woody species can benefit by escaping summer browsing by livestock.

4) Rotation—As described in Elmore (1992), a pasture in the rotation system is rested for a portion of the growing season, similar to the early rotation grazing system. A pasture might be grazed in spring in year 1, and summer in year 2. Again, herbaceous plants typically benefit, but the woody species decline as a result of the summer utilization (table 3.173). An acceptable use of this system would be on low gradient, wide valley sites dominated by herbaceous grasses.

Other grazing systems listed in table 3.173 include season-long, spring and fall, and spring and summer. In general, these grazing systems do not provide for successional advancement of riparian vegetation on any stream system listed in table 3.173.

Using the above-presented options, strategies, and grazing systems, there are numerous case study examples of riparian area improvement in the Basin (Chaney and others 1990, 1993; Kinch 1989). For many of the successful case studies, exclusion of livestock (two years or more) initiated recovery, thereby enhancing the effects of improved management implemented thereafter.

Western Juniper Expansion

This subsection is a summarization of Karl and Leonard (1995), which was derived primarily from Eddleman and others (1994). Unless otherwise cited, text in this subsection originated from Eddleman and others (1994).

Historical to current trends—Western juniper is a relatively small to medium-stature native tree of the Pacific Northwest region. The areal extent of the historical and current distributions of western juniper in the Basin lies primarily in eastern Oregon (maps 3.45 and 3.46). In the historical period, before settlement of the Basin by Euro-Americans, western juniper existed in relatively open, savannah-like woodlands (Nichol 1937, in Miller and Rose 1995; West 1988, in Miller and Rose 1995) or was confined to rocky surfaces or ridges [(Barney and Frishknecht 1974, Cottam and Stewart 1940, Hopkins 1979, and Johnson and Simon 1987), in Miller and Rose 1995]. The rocky surfaces or ridges were characterized by well-drained, shallow soils that produced relatively little

Table 3.173—Generalized relationships between grazing strategy, stream system characteristics, and riparian area variables (shrubs, herbs, and banks) (adapted with permission from Buckhouse and Elmore 1991).

understory herbaceous vegetation and did not burn frequently. The juniper woodland cover type portrayed in maps 3.45 and 3.46 generally represents woodlands found on these rocky surfaces or ridges. In the Basin, historical extent of the juniper woodland cover type was estimated at 0.11 percent, whereas the current period extent was slightly greater, at 0.14 percent (table 3.125). The juniper-sagebrush cover type portrayed in maps 3.45 and 3.46 generally represents western juniper where it existed in savannah-like woodlands maintained by relatively frequent fires. These woodlands typically had an understory that included various sagebrush species. Since the late-1800s, and more specifically the 1880s on Steens Mountain (Miller and Rose 1995) in the Northern Great Basin ERU, western juniper increased in density and distribution. Western juniper has expanded into mountain big sagebrush, low sagebrush, quaking aspen, and riparian communities. This expansion is reflected in the trends of the juniper-sagebrush cover type between historical and current periods. The historical extent of the juniper-sagebrush cover type in the Basin is estimated at less than 1 percent, whereas the current period extent is substantially greater (approximately 2%; table 3.125).

The interaction between climate and fire was likely causal in western juniper expansion and contraction before the historical period. Western juniper tended to expand its distribution during climatically cooler and wetter periods, while its distribution contracted during climatically warmer and drier periods. Fire can kill western juniper, particularly young individuals and those less than 4 meters in height.

After Euro-American settlement, the interaction between climate and fire remained operative in western juniper expansion, but excessive livestock grazing pressure entered as an additional causal factor. Climate from the mid-1800s through the early-1900s was characterized by relatively mild and wet winters and cool, wet springs, which were favorable for western juniper growth. Excessive livestock grazing pressure in the late-1800s and early-1900s contributed to a reduction in fuels that could carry fire, thereby decreasing fire frequency. In addition, fire suppression policies have generally lengthened fire-return interval.

Eddleman and others (1994) propose that the historical, excessive livestock grazing pressure played a larger role in fire frequency reduction compared with active suppression. Excessive livestock grazing pressure, through consumption of herbaceous species, also contributed to an increase in density and canopy cover of shrub species, primarily sagebrush. The microenvironment beneath shrub canopies is favorable for western juniper seedling establishment and growth. Western juniper is becoming established with and without livestock grazing, but evidence implicates excessive livestock grazing pressure in hastening its establishment rate.

Effects of western juniper expansion and control on selected ecosystem attributes— Plant communities that are susceptible to invasion by western juniper can be dominated by any of these species: mountain big sagebrush, Basin big sagebrush (*Artemisia tridentata tridentata*), low sagebrush, aspen, bitterbrush, mountain mahogany, Idaho fescue (*Festuca idahoensis*), ponderosa pine, bluebunch wheatgrass, stiff sagebrush (*Artemisia rigida*), Wyoming big sagebrush, Basin wildrye (*Elymus cinereus*), and threetip sagebrush (*Artemisia tripartita*). The concerns with expansion of western juniper into the above-mentioned plant communities relate to understory productivity, biodiversity, hydrology, and wildlife habitat. As western juniper increases in density in these plant communities, understory vegetation production declines. Conversely, after control (reduction in abundance) of western juniper, productivity of understory species typically increases. The effects of western juniper expansion and excessive livestock grazing pressure on understory productivity are confounded (ascribing the proportion of a decline in understory productivity to western juniper expansion or excessive livestock grazing pressure independently, when both are acting together is difficult). However, excessive livestock grazing pressure in this context is believed to hasten the decline of understory productivity.

Although production of understory vegetation typically increases after western juniper control, the species that respond favorably are not always desirable and the positive recovery response is species-specific. Undesirable species, such as cheatgrass, medusahead, and exotic forbs such as knapweeds, can respond favorably to western juniper removal, depending on the technique used for removal, and whether or not these species were present on-site before removal. Fire, particularly if used to control western juniper, can result in an enhancement of exotic, flammable annual grasses such as cheatgrass and medusahead.

Plant species that exist commonly in western juniper woodlands include 9 annual grasses, 48 annual or biennial forbs, 82 perennial forbs, 20 perennial grasses, 3 sedges, 13 shrubs, and 1 tree (ponderosa pine). In addition to flora, 2 amphibian, 53 bird, 29 mammal, and 13 reptile species can regularly be found in western juniper communities (see appendix 3-J for details). Species lists of non-vascular plants, invertebrates, or microorganisms associated with western juniper have not been compiled to our knowledge. Thus, estimates of species richness of western juniper or woodland communities are incomplete, and have yet to be provided for pre- and post-western juniper presence or expansion (Karl and Leonard 1995). For this reason, speculation (for example, Belsky 1995) that western juniper does not reduce biodiversity cannot be supported or refuted definitively with scientific evidence at this time. There is recent evidence that floral species richness (especially forbs) is significantly greater on sites that have received western juniper control, compared with sites where western juniper remains intact (Bates and others 1994). In addition, Burkhardt and Tisdale (1969), in Oregon Department of Fish Wildlife (1993); and West and Van Pelt (1986), in Oregon Department of Fish Wildlife (1993), report that as juniper species (including western juniper) increase in density and canopy cover, plant species richness and abundance declines.

Biodiversity incorporates several levels of biological organization including genetic, population/species, community/ecosystem, and landscape or regional (Noss and Cooperrider 1994). At the landscape level, the expansion of western juniper woodlands might be adding to, rather than detracting from, landscape diversity because these woodlands contribute to the mosaic and pattern of plant communities on the landscape. However, there presumably is a threshold beyond which the expansion of western juniper woodlands no longer enhances landscape diversity. Whether expansion of western juniper woodlands continues or not, the dilemma from a biodiversity perspective relates to how much acreage of western juniper woodlands, of various densities, composition, and structural stages, we wish to maintain on the landscape. Biodiversity at the population/species level, within western juniper woodlands, would be expected to change, often downward, as these woodlands develop successionally (Karl and Leonard 1995).

The expansion of western juniper into sagebrush-grassland communities and subsequent changes in community structure will undoubtedly alter faunal diversity, because faunal diversity in western juniper woodlands probably is tied more closely to structural diversity than to plant species composition (Oregon Department of Fish and Wildlife 1993). Western juniper communities are highly variable in structure, ranging from open stands with a relatively diverse assemblage of shrubs, grasses, and forbs, to dense woodlands with meager understory vegetation. While the structure provided by western juniper does provide thermal cover for large native herbivores such as mule deer, the expansion of western juniper into sagebrush-grassland communities, and the ensuing alteration of the understory structure, can result in reduced forage availability for mule deer and a decline in the quality of their winter range (Liverman 1993, in Haugen 1993). Alteration of low and big sagebrush structures attributable to the expansion of western juniper has the potential to be deleterious to sage grouse populations, because sage grouse have generally been associated with low and big sagebrush

communities. Additional studies designed to address faunal population responses to western juniper expansion and removal would be helpful. The relationships between fauna and (1) density and canopy cover of western juniper; (2) understory composition; and (3) vegetation structure are poorly defined. The effects of patch cutting, thinning, or commercial harvest of western juniper (Swan 1995) on faunal populations are primarily speculative.

The effects of western juniper on hydrology relate to precipitation interception and infiltration, water runoff, and erosion. The western juniper canopy intercepts precipitation, resulting in restricted precipitation input to the soil surface (more so in low-intensity storm events than in high-intensity events). On sites characterized by western juniper with sparse understory vegetation and particularly in gaps between canopies, western juniper has been implicated in reduced infiltration and increased runoff and erosion. More hydrological research conducted in western juniper woodlands is needed to elucidate the role of western juniper in hydrology. Most hydrological research regarding juniper has been conducted in pinyon-juniper woodlands of the southwest United States.

Sediment yields in pinyon-juniper woodlands are apparently greater on xeric sites (characterized by south aspects and shallow soils) compared with more mesic sites (Wilcox and others 1995, in Wilcox and Davenport 1995) attribute this to less understory cover on the xeric sites. With caution, Wilcox and others (1995, in Wilcox and Davenport 1995) propose that xeric sites in western juniper woodlands also are more susceptible to erosion than are more mesic sites. Their caution arises from extrapolating results from pinyon-juniper woodlands in the southwest United States to western juniper woodlands in the Basin. High-intensity summer storms, which are prevalent in the southwest United States and produce the majority of annual runoff on pinyon-juniper woodlands, are somewhat less prevalent in the Basin. Based on results from studies performed on sagebrush sites in the Basin (southwestern Idaho), Wilcox and Davenport (1995) surmise that most runoff in western juniper woodlands is frozen soil runoff that is generated from snowmelt and rain-on-snow events, in contrast to summer runoff in pinyon-juniper woodlands. However, snowcover in western juniper woodlands typically is not present for long periods.

Wilcox and Davenport (1995) proposed several hypotheses regarding runoff and erosion in western juniper woodlands: (1) Although an increasing density and distribution of western juniper will often increase site erodibility, erosion rates in western juniper woodlands are low and are primarily attributable to winter season, frozen soil runoff, or low energy storms. Little sediment yields should be expected. There is an exception to this hypothesis however. Miller (1995, in Wilcox and Davenport 1995) speculates that erosion rates in western juniper woodlands can be great in portions of central Oregon, particularly on sites characterized by erodible soils and steep, south facing slopes. Intense summer storms can occur in this area. (2) Most runoff and erosion is concentrated in the intercanopy zones as a result of raindrop impact, especially in areas having a preponderance of bare soil. (3) Sediments resulting from erosion are redeposited rapidly, before they are transported great distances. Runoff and erosion is scale dependent and generally diminishes as the scale increases. Although runoff and erosion might be greater locally and on-site as a result of western juniper expansion, the distant, off-site impacts are likely to be minimal. In pinyon-juniper woodlands, sediments and associated nutrients that are produced are likely to be redeposited in riparian areas, which might be an off-site benefit (Gifford 1985, in Wilcox and Davenport 1995). Whether or not this sediment redeposition in riparian areas is a net benefit to the entire ecosystem is arguable and subject to testing. An exception to this scale hypothesis is when gully erosion occurs. In this case, erosion might actually increase with scale and off-site redistribution of sediment might be substantial.

The hydrological effects of livestock grazing are not easily differentiated from the hydrological effects attributed to an increased density of western juniper. However, where livestock grazing has contributed to the decline in understory vegetation, it probably has also contributed to increased runoff and erosion (Evans 1988, in Belsky 1996; Karl and Leonard 1995).

Control of western juniper has been promoted to increase water yield, decrease erosion, and decrease sediment yield. One of the major hypotheses that was an impetus for research on the effects of control of pinyon-juniper woodlands was that water yield would increase (Wilcox and Davenport 1995). However, little if any increase in water yield resulted from pinyon-juniper removal in Arizona. In addition, control treatments that were applied, including herbicides and mechanical removal, had little effect on runoff and erosion (Wilcox and Davenport 1995).

As previously mentioned, most runoff in western juniper woodlands is surmised to be generated in winter and early spring, and characterized by a low sediment yield. Based on this conjecture, the assumption could be made that conversion of western juniper woodlands would result in little mitigation of erosion and sediment yield. There are compelling reasons to reduce juniper in some locations, but Wilcox and Davenport (1995) propose that improvement in water quality is not a compelling reason because eroded sediments apparently are redeposited rapidly. Also mentioned previously, this redeposition of sediments is speculated to most likely occur in riparian areas. Land managers (for example, Swanson 1996[3]) remain skeptical however, about the lack of water quality improvement resulting from juniper reduction. Swanson and other land managers have observed numerous cut and adjacent uncut western juniper stands, where sheet and rill erosion was prevalent on the uncut compared with the cut sites. The dilemma appears to focus on scale. We propose that site-specific, fine scale observations by land managers generate the skepticism toward the lack of water quality improvement; Wilcox and Davenport (1995) propose that the lack of water quality improvement associated with juniper reduction is applicable at the watershed scale. Thus, it appears that at a more localized level, juniper control can reduce sheet and rill erosion (Swanson 1996[3]), while at the watershed scale, the evidence is not definitive.

Control of western juniper expansion—Fire, tree cutting, livestock grazing, and revegetation (post-control of western juniper), are potential techniques for constraining western juniper expansion. The primary mortality factor operating in western juniper stands is fire. As mentioned previously, western juniper trees less than 4 meters in height are particularly susceptible to mortality from fire. As tree height increases however, greater fire intensities are required to cause mortality. Western juniper stands with a high canopy cover (relative to the site) typically burn with less predictability because fuel is lacking between and beneath canopies. Thus, as a control agent, fire is particularly effective on sites which have undergone recent expansion by western juniper. Fire on these sites reverses the succession of herbland and shrubland to western juniper woodland, thereby slowing its expansion. Fire-return intervals of 30 to 40 years have been proposed as adequate to prevent western juniper expansion into sagebrush-grassland communities (Burkhardt and Tisdale 1976).

Although fire can be an effective control agent for western juniper, it can also enhance the abundance and expansion of exotic plant species. Cheatgrass, medusahead, and knapweeds (for example diffuse knapweed) are exotic species that can be found in western juniper woodlands. These exotic species were not a component of herbland, shrubland, and woodland physiognomic types representative of the biophysical template. The use of fire in western juniper woodlands can provide acceptable microsites for establishment, and enhance the abundance, of these exotic species, in comparison with native species. Thus, reintroduction of fire

[3] Personal communication. 1996. John Swanson, Acting District Ranger, U.S. Department of Agriculture, Forest Service, Paulina Ranger District, Ochoco National Forest, 171500 Beaver Creek Road, Paulina, OR 97751.

into western juniper woodlands that have been free from fire for long periods might not result in plant assemblages typically associated with native fire frequencies and the biophysical template.

Research is providing evidence for sizeable storage of nutrients aboveground in western juniper tissue, especially nitrogen, phosphorous, potassium, calcium, and magnesium. On inherently nutrient-deficient sites that support western juniper woodlands, there is speculation that the volatilization of nutrients within the aboveground tissue of western juniper will exacerbate an already marginal situation (Belsky 1995). Fire in this instance could cause the vegetation to cross a threshold into a more degraded, stable state (Laycock 1991, in Belsky 1995). An example of this more degraded, stable state is an exotic annual grass dominated site. The cutting and removal of western juniper trees might also substantially reduce the nutrient capital of a nutrient-limited site. Research has yet to provide estimates of nutrient loss attributable to fire (or tree cutting and removal) in western juniper stands. This research is needed to aid land managers in site-specific decision making regarding control of western juniper with fire or tree cutting, and its effects on nutrient capital.

Western juniper slash left on site after cutting should ameliorate the potential effects on available nutrients. Washington and Eddleman (1995) and Washington (1996) evaluated a western juniper cutting and slash distribution technique in western juniper woodlands in central Oregon that were characterized by a meager understory of perennial plants. The technique was used in conjunction with post treatment understory seedings. Steps involved with the technique included broadcast seeding or transplanting of desirable perennial grasses, cutting of western juniper, and subsequent distribution of the western juniper limbs (slash) across the soil surface. Sometimes the understory was burned before broadcast seeding or transplanting, particularly if the understory was dominated by annual, exotic grass species such as cheatgrass and medusahead. Western juniper slash resulted in enhanced seed production and/or establishment of seeded perennial grasses. The causal mechanism was speculated as amelioration of microsite conditions, especially soil water and temperature, that results in enhanced establishment and growth of perennial species. Burning of the exotic annual grasses before seeding or transplanting can result in increased establishment and seed production of perennial grasses. Hydrologically, the use of a similar technique in the southwest United States reduced runoff and erosion, compared with sites where slash and debris were removed (Gifford 1975, in Wilcox and Davenport 1995; Wood and Javed 1991, in Wilcox and Davenport 1995).

Preliminary results from Washington (1996) and Washington and Eddleman (1995) are promising with regard to understory revegetation efforts after control of western juniper woodlands. The western juniper cutting and slash distribution technique shows promise for use on sites where burning alone cannot be expected to control western juniper. These unpublished research results remain site-specific and preliminary; refinement of the technique through additional experimentation is warranted.

Additional research focusing on livestock grazing and its effects on western juniper demography is needed, particularly within existing western juniper woodlands, woodlands that have received western juniper control, and on sites that are susceptible to western juniper expansion. However, in the interim, biological, physiological, and ecological research that has been conducted in woodlands, combined with research on plant response to herbivory, can provide insight into the effects of livestock grazing on western juniper demography.

Using a combination of research information similar to that proposed above, Eddleman and others (1994) proposed livestock grazing strategies that would be least likely to have deleterious effects on understory vegetation and western juniper expansion. These livestock grazing strategies were proposed for four types of western juniper sites and are summarized below by site type. For each site type, discussion will focus on the objectives, the options involved, and the rationale for the livestock grazing strategy.

The livestock grazing strategies presented by Eddleman and others (1994) are speculative, yet are based on observations and findings from many years of research in western juniper ecosystems. These strategies should be regarded as a foundation for discussion and generation of hypotheses for future research into the effects of livestock grazing on western juniper demography.

Site 1. Young woodlands (dominated by trees < 100 years old) with a canopy cover near or at the site maximum, and on shallow soils.

Livestock Grazing Strategy

Objectives:

1) Vigorous, desirable, forage plants

2) Understory plant canopy cover

3) Well dispersed plants across the site

4) Maximum litter cover and dispersion

Options Involved:

- Light utilization of understory plants (not exceeding 15-25%) by livestock when these plants are near maturity, or after maturity.
- Repeated light utilization during the late growth period, permissible only in years when precipitation received during the typical growth period sustains normal to above-normal production. Caution with regard to repeated light utilization should be exercised because the precipitation timing and interval that sustains normal to above-normal production varies by understory species and there is little species-specific information presently available.

Rationale:

Where dry conditions or shallow soils (generally < 30 cm in depth) exist, there is little soil storage of precipitation and the availability of soil water for understory growth becomes limiting in amount and duration. Characteristics of western juniper that exacerbate the potential for understory growth include: (1) the interception of precipitation by the canopy and litter layer, (2) the use of stored soil water from intercanopy areas before understory species commence growth and during their growth periods, and (3) the use of incident precipitation that falls during summer dormancy of understory species. Grazing of understory species during the growth period under the above-stated conditions is deleterious because plant loss of vigor, density, and ground cover is likely. Effective precipitation for growth is restricted mainly to fall, winter, and spring; thus, the window of water and nutrient availability is optimal only early or late in the growing season, and is of short duration. Grazing during the early portion of the growing season would appear to be damaging to understory plant vigor because the short window of soil water and nutrient availability might close and prevent regrowth. Fall precipitation might stimulate regrowth of understory plants that are nearing maturity, and permit light grazing (10 to 15 % utilization).

The deleterious effects of excessive grazing pressure on understory species will probably not be ameliorated by rest (absence of grazing) of one, two, or even three years because during the grazed periods western juniper could incrementally gain in site dominance and impede future recovery of understory species during ungrazed periods. The importance of rest in permitting recovery will increase if rest is concurrent with wet years.

Grazing of plants after maturity has effects on the insulating qualities of the plants relative to the soil, which in turn has hydrological effects on the site. Understory plants insulate the soil from soil temperature fluctuations and moisture evaporation. Understory plants lose their insulating effectiveness if they sustain excessive grazing pressure and do not regrow before winter. Wet soil surfaces in intercanopy areas of western juniper woodlands, characterized by a lack of plant or snow insulation, can develop concrete frost in the cold portion of winter, and subsequently freeze and thaw diurnally in late winter and early spring. Precipitation can run off of soils with concrete frost because infiltration rates are nearly zero. Freeze-thaw activity pulls water to the soil surface where it can evaporate. Temporary warm winter periods in

western juniper woodlands, when coinciding with unfrozen soil, can result in evaporation of surface soil moisture.

Precipitation is typically not sufficient to fully recharge the soil and counteract the evaporative loss in western juniper woodlands that have sustained grazing in the late growing season. Soil water storage and the amount of water that will be available for plant growth in the subsequent growing season could therefore be reduced on shallow soils with inherent low water storage capacity.

Conversely, some shallow soils, particularly those associated with the low sagebrush PVTs, can become saturated during the winter. Added inputs of precipitation or snowmelt on these saturated shallow soils can result in runoff. Plant cover and dispersion, and litter, can reduce sediment transport in this runoff.

Site 2. Young woodlands (dominated by trees < 100 years old) on deep soils.

Livestock Grazing Strategy

Objectives:

Objectives 1 through 4 from Site 1 are again pertinent, with an additional fifth objective:

5) Sustained growth of desired understory plants during the growing season

Options Involved:

On sites characterized by prevalent understory grasses:

- Same strategy as previously mentioned for Site 1.

On sites characterized by a declining grass base:

- Light utilization of understory plants (not exceeding 15-25%) by livestock, and substantial periods of rest.

On sites characterized by virtually no vascular plant cover:

- Non-use.

On sites characterized by full occupancy by annual grasses such as cheatgrass or medusahead:

- Carefully planned grazing or non-use.

Rationale:

Potentially greater amounts of available soil water can be stored in a deep soil compared with a shallow soil. This translates to greater potential biomass production of understory species and greater potential for regrowth and plant recovery from grazing. Healthy understory plants and their canopy cover promote detention of surface water, absence of concrete frost, and dispersion of plant biomass over the site. Grazing pressure that results in high levels of utilization after plant maturity can diminish canopy cover and thus restrict water storage during the winter.

Water storage during the winter, supplemented with additional precipitation in the spring, can sustain plant growth over relatively long durations. Successive, light removal of herbage by grazing should be possible under these conditions and still not adversely affect either plant vigor or the nutrient pool of the plant. Bitterbrush, other shrubs, and forbs would not likely be utilized excessively, and competition of annual grasses with perennial grasses would not likely be increased. The probability of interference of western juniper with understory species is increased if grazing pressure results in utilization that delays plant regrowth initiation.

Sites that support a declining grass base will probably require light use and extended rest periods to permit plant recovery. Sites that support virtually no vascular plant cover cannot legitimately accommodate any grazing prescription except non-use. There should be little expectation for understory species recovery even in the absence of grazing. Full site occupancy by annual grasses (such as cheatgrass or medusahead) mandates carefully planned grazing or non-use because grazing utilization of these species can result in sediment loss from the site during periods of potentially high runoff.

Site 3. Woodlands subsequent to western juniper control.

Livestock Grazing Strategy

Objectives:

Objectives 1 through 5, previously mentioned, are also pertinent, with an additional sixth objective:

6) Rapid site dominance by desired understory species

Options Involved:

On sites that support prevalent understory vegetation at the time of control:

- Non-use in year 1 (post-treatment); defer grazing until seed set in year 2.
- Repeated light utilization, rest, rotated seasonal utilization, and deferred utilization are options permissible within a grazing strategy.

On sites that support moderate understory vegetation at the time of control:

- Non-use in year 1 and 2 (post-treatment); defer grazing until seed set in year 3.
- Repeated light utilization, rest, rotated seasonal utilization, and deferred utilization are options permissible within a grazing strategy.

On sites that support little if any understory vegetation at the time of control:

- Non-use until year 3 or 4 (post-treatment), when recovery of plant vigor is apparent, including reproduction and seedling establishment.
- Single or repeated light utilization when plants are nearing maturity, or light utilization after maturity, possibly until year 5 or 6 (post-treatment).
- Repeated light utilization, rest, rotated seasonal utilization, and deferred utilization are options permissible within a grazing strategy.

On sites that are seeded:

- Non-use until year 2, 3, or 4 (post-treatment) when seedling establishment is attained and a competitive population is present.
- Single or repeated light utilization when plants are nearing maturity, or light utilization after maturity, possibly not until year 4, 5 or 6 (post-treatment).
- Repeated light utilization, rest, rotated seasonal utilization, and deferred utilization are options permissible within a grazing strategy.

Adjustments in this livestock grazing strategy might be necessary because control of western juniper could be accomplished by several different techniques, each of which affect site responses to grazing management somewhat differently. Adjustment in the grazing strategy might be necessary to foster certain species compositions over others. For example, there is potential for this grazing strategy to accelerate invasion of exotic plant species, such as cheatgrass, medusahead, or noxious weeds.

Control of western juniper does not equate to eradication. Western juniper seedlings will undoubtedly be present in uneven-aged stands that sustain juniper control. A sizeable seed bank of western juniper will undoubtedly exist in even-aged or uneven-aged stands that sustain juniper control. These mechanisms ensure future site dominance by western juniper. Subsequent periodic control with burning, tree cutting, or commercial harvest (not yet practiced on Federal land) will maintain non-woodland or open (minor canopy cover) woodland conditions.

Rationale:

Understory species typically respond positively in production after control of western juniper. Herbaceous production on a species-specific level typically peaks at year 2 or 3 (post-control of western juniper). Subsequent herbaceous production typically declines to a level somewhat greater than the pre-control level. Recovery time might be delayed on sites that support moderate to low quantities or no understory vegetation because

species would need to establish new populations from newly formed seed banks or other propagules.

The probability and amount of understory regrowth are increased on these sites because of enhanced soil water availability attributable to the control of western juniper (that is, reduction in photosynthetic tissue and transpirational leaf area). Enhanced soil water availability extends the length of the growing period: observations indicate continuous spring, summer, and fall understory growth in year 1 and 2 (post-control of western juniper). Grazing pressure resulting in light utilization will ensure that some photosynthetic tissue remains after grazing from which regrowth can initiate, rather than total denudation of plants and regrowth being initiated through new tiller and leaf material.

Site 4. Sites susceptible to western juniper encroachment and dominance.

Livestock Grazing Strategy

Objectives:

Objectives 1 through 5, previously mentioned, are pertinent here, with three additional objectives:

7) Maintain site dominance by desired understory species

8) Prevent rapid dispersal of western juniper seed originating from upslope

9) Limit big sagebrush density

Options Involved:

Numerous options within grazing strategies previously mentioned are applicable here. The strategy selected will depend on soil depth of the sites, and visual trend and composition (for example, stable trend, declining trend, dominance by annual grasses, virtually no herbaceous biomass) of the herbaceous understory vegetation.

Rationale:

The rate of western juniper encroachment and dominance will be constrained if a vigorous grass understory is maintained. A vigorous grass understory will restrict surface flow of water during the late fall, winter, and early spring periods, which are typical seed dispersal periods for western juniper. A decline in western juniper recruitment will result.

As previously mentioned, big sagebrush provides a safe site for establishment of western juniper seedlings. Sagebrush control measures might be necessary on some sites to reduce sagebrush densities to a reasonable level. The maintenance of a vigorous understory will restrict establishment of sagebrush and western juniper seedlings.

Exotic Plants-Noxious Weeds

This subsection is primarily a summarization of Karl and others (1995), an ICBEMP report which focused on exotic plants that have proven to be problematic on Basin rangelands and riparian areas. Additional information regarding exotic plants on forested lands is incorporated into this subsection, primarily from the Invaders database (ICBEMP Invaders database 1995[4]).

Historical trends—The Basin has experienced numerous exotic plant invasions in the last 100 years [(Franklin and Dyrness 1973, Yensen 1981, and Young and others 1972), in Mack 1986]. Presently, there are approximately 862 species of exotic plants existing within the Pacific Northwest (Washington, Oregon, Idaho, Montana, and Wyoming; Rice 1994). Nearly all of these 862 species inhabit the Basin. These 862 exotic plant species represent 43 percent of the estimated 2,000 exotic plant species present in the entire United States (U.S. Congress, Office of Technology Assessment 1993, in Vitousek and others 1996).

[4] ICBEMP Invaders database. 1995. On file with: U.S. Department of Agriculture, Forest Service; U.S. Department of Interior, Bureau of Land Management, Interior Columbia Basin Ecosystem Management Project, Walla Walla, WA 99362.

Many of the exotic plants existing within the Basin originated in the Mediterranean region. The climate of the Mediterranean region (wet, cool autumns and winters; and dry, hot summers) is similar to the climate of the Basin, particularly the portion of the Basin that lies west of the Rocky Mountains. Thus, many exotic plants are adapted to the Basin climate (Trewartha 1981, in Mack 1986; Young and others 1972, in Mack 1986).

Euro-American settlement of the Basin in the late-1800s facilitated the invasion and expansion of exotic plants. Agricultural practices were the major avenue by which exotic plants initially entered the Basin. The seed of many exotic plants was a contaminant of crop seed, and some exotic plants were deliberately introduced to provide livestock forage. The severe depletion of native bunchgrasses on Basin rangelands, caused by livestock overgrazing and trampling, was often the impetus for deliberate introductions of forage species (Mack 1981, in Mack 1986). Thus, the land-use change from wildlands to agriculture—a transition that was the most prevalent change between the historical and the current periods—has promoted invasions of numerous exotic plants in the Basin. Not surprisingly, this change in land use has promoted invasions of exotic plants on a global scale as well (Vitousek and others 1996).

Noxious weeds: a subset of exotic plants—Of the 862 exotic plants existing within the 5-state region (Washington, Oregon, Idaho, Montana, and Wyoming) of the Pacific Northwest, 115 species have been legally declared as "noxious weeds" by at least one of the five states. "Noxious" is a legal classification and not an ecological term. Plants that can exert substantial negative environmental or economic impact can be designated as "noxious" by various governmental agencies. Of the 25 exotic plant species listed in table 3.13, 24 are legally declared noxious in at least one of five Basin states. These 24 noxious weeds represent a subset of the 115 noxious weeds.

Success of exotic plants-noxious weeds—Present distributions of many exotic plants within the Basin, including the noxious weeds, are increasing rapidly and in some cases exponentially (Asher 1994, Rice 1994, Rice and Rider 1995). This rapid rate of expansion is partly attributable to the life history of exotic plants. Exotic plants are often opportunists, and many are pioneer, colonizing species. They are frequently one of the first species to arrive and colonize areas that have experienced soil-surface disturbance or areas that lack plant cover. Their establishment and spread is aided by disturbance to the soil surface (Baker 1986, Bazzaz 1986). Exotic plants that are characterized as having an opportunistic, colonizing life history—referred to as "colonizers" by Bazzaz (1986)—are typically prolific producers of disseminules and often are adapted to long-distance dispersal by means of vehicles, wind, wildlife, livestock, water, or machinery. They usually germinate under a wide variety of conditions, establish quickly, exhibit fast seedling growth, and out-compete native species for water and nutrients.

Other exotic plants, such as the noxious weeds spotted knapweed, yellow starthistle, and leafy spurge, can be categorized as "invaders" (Bazzaz 1986). Invaders can establish within relatively intact vegetation cover, and displace the native species without the aid of soil-surface disturbance. While noxious weeds can be colonizers or invaders or both, depending on the plant community, it is noteworthy and perhaps indicative of their noxious weed status that many of them act as invaders. For example, spotted knapweed, yellow starthistle, and leafy spurge have exhibited the ability to invade relatively undisturbed sites, including wilderness areas and National Parks (Asher 1994, Tyser and Key 1988).

Reasons why exotic plants-noxious weeds are problematic—Exotic plants, including noxious weeds, represent biological invasions. As agents of global change, exotic plants were rated as highly as climate change by Vitousek and others (1996). The invasive potential of exotic plants can alter the biophysical template by altering ecosystem processes. Vitousek and others (1996) listed examples of potentially altered ecosystem processes including: (1) primary productivity, (2) decompo-

sition, (3) hydrology, (4) nutrient cycling, and (5) natural disturbance regimes. Alteration of these processes by exotic species can lead to displacement of native biota.

The invasion of exotic plants can change the structure, composition, and successional pathways of ecosystems at various scales (from the landscape element to subregional scale). An example of the subregional scale is the invasion and dominance of cheatgrass and/or medusahead in the Snake River Plains of the Owyhee Uplands ERU. The establishment of potential vegetation that is representative of the biophysical template can be prevented by exotic plant invasion. In effect, potential vegetation can be changed from a native plant type to an exotics type. The reduction in biodiversity at all scales is a possible response of this change in potential vegetation. Indeed, Billings (1994) warns that in the cheatgrass-dominated areas of the Intermountain region, including the Snake River Plains of the Owyhee Uplands ERU, some native biota are in danger of extirpation at the local or regional scale.

Although studies concerning the effects of exotic plants on hydrologic systems are generally lacking, accumulating evidence is revealing that invasions of exotic plants into native plant communities can result in increased surface runoff and sediment yield, particularly at the plot scale (Lacey and others 1989). Watershed-scale studies of the hydrological effects of exotic plant invasion would be helpful in clarifying the effects to aquatic ecosystems.

The fact that exotic plants can function as agents of change of native succession/disturbance regimes has frequently been addressed in this chapter. Exotic annual grasses, for example cheatgrass, medusahead, and ventenata, can produce relatively greater amounts of flammable, fine fuels compared with native herbaceous species. Susceptibility to wildfire tends to increase in the effected cover types as fine-fuel loads become greater, thus shortening the fire-return interval. Native plants that are not adapted to the shortened fire-return interval cannot sustain their populations. As native plant populations decline, exotic annual grasses incrementally gain in dominance, further perpetuating the shortened fire-return interval.

Conversely, the presence of some exotic forbs might lengthen fire-return intervals. Bushey (1995) reports that plant communities dominated by diffuse knapweed or spotted knapweed are difficult to burn because of a lack of fine fuels. Bushey (1995) speculates that the lack of fine fuels is attributable to allelopathy by these forbs. Another causal mechanism might be the aboveground morphology of these forbs, which in comparison to graminoids is skewed toward greater stem material production rather than leaf production. Allelopathy and prevalence of stem material would reduce the likelihood of fire spread between plants. Experimental studies would aid in clarifying the relation of exotic forbs to fire and disturbance regimes.

Susceptibility of broad-scale cover types to invasion, and broad-scale distribution of 25 selected exotic plants—Dewey and others (1991) propose that "The precision and usefulness of federal weed control Environmental Assessment (EA) and Environmental Impact Statement (EIS) documents would be significantly improved by knowing the exact location and extent of lands vulnerable to specific noxious weeds." We endeavored to do just that by developing a Susceptibility to Invasion Index for 38 broad-scale Basin cover types and characterizing their susceptibility to invasion by the 25 focal exotic plants (table 3.174).

Of the 25 exotic plant species assessed in Karl and others (1995), 11 exhibit a somewhat restricted county distribution in the Basin; and 14 exhibit a widespread county distribution in the Basin (table 3.13). County distributions for widespread species ranged from 48 counties for oxeye daisy (*Chrysanthemum leucanthemum*) to all 97 counties located within the five Basin states (Washington, Oregon, Idaho, Montana, and Wyoming) for Canada thistle and cheatgrass. County distributions for the somewhat restricted species ranged from four counties for squarrose knapweed (*Centaurea virgata*) to 55 counties for yellow starthistle.

County-distribution maps for these 25 species can be found in Karl and others (1995) and Rice and Rider (1995).

The susceptibility of Basin cover types to invasion, and distributional patterns of the 25 focal exotic plants are described in detail as follows:

(A) Exotic plants with somewhat restricted distributions:

Common crupina (*Crupina vulgaris*)

The distribution of common crupina is disjunct with populations existing in Washington, Oregon, and Idaho. Common crupina is particularly prevalent in north-central Idaho, where the Columbia Plateau, Blue Mountains, and Central Idaho Mountains ERUs meet. Sites that are particularly susceptible to invasion in the aforementioned ERU convergence area and presently support populations of common crupina are southern slopes in steep canyon grasslands (for example, the wheatgrass bunchgrass and fescue-bunchgrass cover types; rated of moderate susceptibility to invasion; table 3.174) and areas at elevations of approximately 300 to 1,000 meters and within a 38 to 76 centimeters annual precipitation zone.[5]

Dyers woad (*Isatis tinctoria*)

Populations of Dyers woad exist throughout the Basin, but distribution by county is scattered. The area of greatest prevalence is in southeast Idaho, in the Snake Headwaters and Upper Snake ERUs. At present, the Northern Cascades, Columbia Plateau, and Northern Glaciated Mountains ERUs are primarily outside the distribution of Dyers woad. Numerous cover types are of high susceptibility to invasion by Dyers woad, including grasslands (fescue-bunchgrass and wheatgrass bunchgrass), shrublands (big sagebrush, low sagebrush, mountain big sagebrush), and agricultural lands (cropland/hay/pasture)(table 3.174).

Halogeton (*Halogeton glomeratus*)

The distribution of halogeton is restricted primarily to southeast Oregon and southern Idaho, in the Northern Great Basin, Owyhee Uplands, and Upper Snake ERUs. Halogeton populations in these ERUs are restricted primarily to (1) elevations of 700 to 2,200 meters, (2) saline soils, (3) annual precipitation zones of approximately 12.5 to 33.0 centimeters, and (4) the salt desert shrub cover type, which is of high susceptibility to invasion by halogeton (table 3.174).

Mediterranean sage (*Salvia aethiopis*)

The distribution of Mediterranean sage lies primarily in Oregon and north-central Idaho. An area of great prevalence is in southeast Oregon, particularly in the Northern Great Basin ERU. At present, the Northern Cascades, Southern Cascades, Northern Glaciated Mountains, Lower Clark Fork, Upper Clark Fork, Upper Snake, and Snake Headwaters ERUs are primarily outside the distribution of this species. The grassland cover types (fescue-bunchgrass and wheatgrass bunchgrass) and the big sagebrush cover type are of high susceptibility to invasion by Mediterranean sage (table 3.174) and support populations of this species.

Medusahead (*Taeniatherum caput-medusae*)

The present distribution of medusahead is in the western portion of the Basin, but medusahead is spreading eastward. Areas of great prevalence are in the Columbia Plateau, Northern Great Basin, Blue Mountains, and Owyhee Uplands ERUs in Oregon and Idaho. Currently, the Lower Clark Fork, Upper Clark Fork, Central Idaho Mountains, Upper Snake, and Snake Headwaters ERUs are primarily outside the distribution of medusahead. Sites that are susceptible to medusahead establishment and support populations are characterized by (1) the presence of vertic soils (soils with a substantial clay component that shrink and

[5] Personal communication. 1995. Peter M. Rice, Research Associate, Division of Biological Sciences, University of Montana, Missoula, MT 59812-1002.

swell from drying or wetting); (2) an annual precipitation zone of 25 to 100 centimeters; (3) an elevation of less than 1,400 meters; and (4) numerous cover types, particularly grassland (wheatgrass bunchgrass and fescue-bunchgrass), shrubland (low sagebrush and big sagebrush), and juniper cover types (juniper/sagebrush and juniper woodland), all of which are of moderate susceptibility to invasion (table 3.174).

Orange and yellow hawkweeds (*Hieracium aurantiacum, H. pratense*)

The distributions of these two species are similar. Both have distributions centered in the Idaho panhandle, northwest Montana, and northeast Washington, in the Northern Glaciated Mountains and Lower Clark Fork ERUs. Sites that are susceptible to invasion by the hawkweeds in the aforementioned locations include elevations exceeding 600 meters and mountain meadows. The herbaceous wetlands and cottonwood/willow cover types are of high susceptibility to invasion by orange and yellow hawkweed, respectively (table 3.174).

Rush skeletonweed (*Chondrilla juncea*)

The distribution of rush skeletonweed primarily lies within the Columbia Plateau, Blue Mountains, Central Idaho Mountains, and Owyhee Uplands ERUs. Areas of great prevalence are in southwest Idaho in the Owyhee Uplands ERU, and in eastern Washington in the Columbia Plateau ERU. Cover types that are of high susceptibility to invasion and support populations of rush skeletonweed are cropland/hay/pasture and exotic forbs/annual grass (table 3.174). Other cover types, rated of moderate susceptibility in table 3.174, that also are of particular susceptibility to invasion are big sagebrush, wheatgrass bunchgrass, and bitterbrush/bluebunch wheatgrass.[6]

[6] Personal communication. 1995. Peter M. Rice, Research Associate, Division of Biological Sciences, University of Montana, Missoula, MT 59812-1002.

Squarrose knapweed (*Centaurea virgata*)

The distribution of this species lies primarily in the Blue Mountains and Owyhee Uplands ERUs in Oregon. Its areal extent in the aforementioned ERUs is minor (< 350 ha in 1990) and is primarily in the Blue Mountains ERU. Cover types that are susceptible to squarrose knapweed establishment and support populations include juniper/sagebrush, juniper woodland, and big sagebrush (Roche and Burrill 1992), all of which are of moderate susceptibility to invasion (table 3.174).

Sulfur cinquefoil (*Potentilla recta*)

The distribution of sulfur cinquefoil primarily lies within the Northern Glaciated Mountains, Upper Clark Fork, Lower Clark Fork, Central Idaho Mountains, and Blue Mountains ERUs. Its distribution is expanding to the west and south, within the Basin. Areas of great prevalence are in the Upper Clark Fork, Lower Clark Fork, and Northern Glaciated Mountains ERUs in the Idaho panhandle and western Montana. Cover types that are of high susceptibility to invasion and support populations of this species in the aforementioned ERUs include grasslands (fescue-bunchgrass, wheatgrass bunchgrass, and herbaceous wetlands), the drier forests (interior ponderosa pine and interior Douglas-fir), and the exotic forbs/annual grass type (table 3.174).

Yellow starthistle (*Centaurea solstitialis*)

The distribution of yellow starthistle includes portions of all ERUs except the Snake Headwaters, and possibly the Upper Snake. The areas of greatest prevalence are in the Columbia Plateau and Blue Mountains ERUs in extreme southeast Washington and the Idaho panhandle, and the Owyhee Uplands ERU in southwest Idaho. Cover types that are of high susceptibility to invasion and support populations of this species in the aforementioned ERUs include grasslands

Table 3.174—Cover type Susceptibility to Invasion Index by 25 exotic plant species (24 legally-declared noxious, plus cheatgrass).

[1] Species codes for exotic plants: Brte = cheatgrass; Canu = musk thistle; Caspp = whitetop; Cedi = diffuse knapweed; Cema = spotted knapweed; Cere = Russian knapweed; Ceso = yellow starthistle; Cevi = squarrose knapweed; Chju = rush skeletonweed; Chle = oxeye daisy; Ciar = Canada thistle; Civu = bull thistle; Crvu = common crupina; Eues = leafy spurge; Hagl = halogeton; Hiau = orange hawkweed; Hipr = yellow hawkweed; Isti = Dyers woad; Lida = dalmatian toadflax; Livu = yellow toadflax; Lysa = purple loosestrife; Onac = Scotch thistle; Pore = sulfur cinquefoil; Saae = Mediterranean sage; Taas = medusahead.

[2]Susceptibility classes: H = High susceptibility to invasion — Exotic plant species is an "invader" and invades the cover type successfully and becomes dominant or codominant even in the absence of intense or frequent disturbance; M = Moderate susceptibility to invasion — Exotic plant species is a "colonizer" and invades the cover type successfully because high intensity or frequency of disturbance impacts the soil surface or removes the normal canopy cover; L = Low susceptibility to invasion — Exotic plant species typically does not establish because the cover type does not provide suitable habitat; and U = Unknown susceptibility to invasion — Herbarium records did not indicate any association between the exotic plant and the cover type, and/or ecological requirements of the exotic plant are not available in the literature, and/or there was a lack of distribution records (for example, herbaria mounts) for the exotic plant, and/or the extent of the cover type in the Basin might be so minor as to prevent or restrict the probability of obtaining distribution records for the exotic plant within that cover type.

(fescue-bunchgrass and wheatgrass bunchgrass), agricultural lands (cropland/hay/pasture), and exotic forbs/annual grass (table 3.174). The areal extent of these highly susceptible cover types within the 30.0-to-63.5-centimeters precipitation zone of yellow starthistle is portrayed spatially in map 3.27. In descending order of extent (percent of ERU), ERUs with greater than or equal to 10 percent extent of lands of high susceptibility to invasion by yellow starthistle are: Upper Snake (29%), Columbia Plateau (27%), Blue Mountains (22%), Snake Headwaters and Upper Clark Fork (14% each), and Central Idaho Mountains and Northern Glaciated Mountains (10% each) (map 3.27). The extent of lands that are of high susceptibility to invasion in the Upper Snake and Snake Headwaters ERUs is notable because the distribution of yellow starthistle has not yet expanded into those ERUs.

(B) Exotic plants with widespread distributions:

Bull thistle (*Cirsium vulgare*)

The distribution of bull thistle includes portions of every ERU. About three-quarters of the Basin counties have confirmed the presence of bull thistle, with unconfirmed counties lying primarily in southern Idaho in the Owyhee Uplands and Upper Snake ERUs. Presence of bull thistle is suspected in these unconfirmed counties, however.[7] Cover types of high susceptibility to invasion by bull thistle include some forest types (Engelmann spruce/subalpine fir, interior Douglas-fir, and western redcedar/western hemlock), grasslands (fescue-bunchgrass), and riparian types (shrub wetlands) (table 3.174).

Canada thistle (*Cirsium arvense*)

At the ERU and county scales, the distribution of Canada thistle is ubiquitous in the Basin. Populations are typically located within a 38- to 76-centimeters precipitation zone. Numerous cover types are of high susceptibility to invasion, including grasslands (fescue-bunchgrass and wheatgrass bunchgrass), riparian types (cottonwood/willow, herbaceous wetlands, and shrub wetlands), and some forest types (aspen, Engelmann spruce/subalpine fir, interior Douglas-fir, and western redcedar/western hemlock) (table 3.174).

Cheatgrass (*Bromus tectorum*)
